Bailey's Head and Neck Surgery—OTOLARYNGOLOGY

FIFTH EDITION

SECTION EDITORS

Basic Science/General Medicine

Shawn D. Newlands
Karen T. Pitman

Rhinology and Allergy

Berrylin J. Ferguson
Matthew W. Ryan

General Otolaryngology

David E. Eibling
Shawn D. Newlands

Laryngology

Milan R. Amin
Michael M. Johns III

Trauma

Grant S. Gillman
Jonathan M. Sykes
Stephen S. Park

Pediatric Otolaryngology

Margaretha L. Casselbrant
Charles M. Myer III

Head and Neck Surgery

Christine G. Gourin
Anna M. Pou

Sleep Medicine

Ryan J. Soose
Edward M. Weaver

Otology

Barry E. Hirsch
Robert K. Jackler

Facial Plastic and Reconstructive Surgery

Grant S. Gillman
Jonathan M. Sykes
Stephen S. Park

Contemporary Issues in Medical Practice

Shawn D. Newlands
Karen T. Pitman

Radiology

Barton F. Branstetter

DISCLAIMER
Care has been taken to confirm the accuracy of the information present and to describe generally accepted practices. However, the authors, editors, and publisher are not responsible for errors or omissions or for any consequences from application of the information in this book and make no warranty, expressed or implied, with respect to the currency, completeness, or accuracy of the contents of the publication. Application of this information in a particular situation remains the professional responsibility of the practitioner; the clinical treatments described and recommended may not be considered absolute and universal recommendations.

The authors, editors, and publisher have exerted every effort to ensure that drug selection and dosage set forth in this text are in accordance with the current recommendations and practice at the time of publication. However, in view of ongoing research, changes in government regulations, and the constant flow of information relating to drug therapy and drug reactions, the reader is urged to check the package insert for each drug for any change in indications and dosage and for added warnings and precautions. This is particularly important when the recommended agent is a new or infrequently employed drug.

Some drugs and medical devices presented in this publication have Food and Drug Administration (FDA) clearance for limited use in restricted research settings. It is the responsibility of the health care provider to ascertain the FDA status of each drug or device planned for use in their clinical practice.

To purchase additional copies of this book, call our customer service department at **(800) 638-3030** or fax orders to **(301) 223-2320**. International customers should call (301) 223-2300.

Visit Lippincott Williams & Wilkins on the Internet: http://www.lww.com. Lippincott Williams & Wilkins customer service representatives are available from 8:30 am to 6:00 pm, EST.

CONTENTS

Contributing Authors xiii
Foreword xxix
Preface xxxi

VOLUME ONE

SECTION I: BASIC SCIENCE/GENERAL MEDICINE 1

1 Surgical Anatomy of the Head and Neck 3
Michael D. Maves

2 Basic Surgical Principles 18
A. Bradley Boland and Emily Rogers

3 Perioperative Management Issues 26
David M. Barrs

4 Operative Technologies 49
Paul G. van der Sloot and Runhua Hou

5 Critical Care 55
Jon D. Simmons and Kimberly A. Donnellan

6 Dynamic Wound Healing 75
Gina D. Jefferson

7 Understanding Data and Interpreting the Literature 86
Richard M. Rosenfeld

8 Outcomes Research and Evidence-Based Medicine 102
Michael G. Stewart

9 Introduction to Otolaryngic Genetics 111
Selena E. Heman-Ackah and Anil K. Lalwani

10 Microbiology, Infections, and Antibiotic Therapy 131
Thuy-Anh N. Melvin and Murugappan Ramanathan Jr.

11 Head and Neck Imaging 141
Tanya J. Rath

12 Surgical Pathology in Otolaryngologic Practice 178
Matthew C. Miller and Christa L. Whitney-Miller

13 Neurology in Otolaryngology 199
Rachel E. Roditi and Benjamin T. Crane

14 Ophthalmology 217
Jean Edwards Holt and G. Richard Holt

15 Anesthesiology 235
Stewart J. Lustik and Shawn D. Newlands

16 Endocrinology 250
Paul G. van der Sloot and Runhua Hou

17 Rheumatologic, Granulomatous, and Other Systemic Diseases Affecting the Head and Neck 267
Valentin D. Marian, Anurag Gandhi, and Shawn D. Newlands

18 Geriatric Otolaryngology 298
David E. Eibling and Sarah H. Kagan

19 Headache and Facial Pain 305
Chase H. Miller and Alfredo S. Archilla

20 Complementary and Alternative Medicine 316
Li-Xing Man and Nicholas C. Sorrel

21 Tobacco Cessation: How-to Guidance and Resources for Practitioners 329
Henry R. Diggelmann and Grant S. Hamilton III

22 Palliative Care and Pain Management 340
Robert M. Taylor and Amit Agrawal

SECTION II: RHINOLOGY AND ALLERGY 357

23 Sinonasal Anatomy and Physiology 359
Randy M. Leung, William E. Walsh, and Robert C. Kern

24 Olfaction 371
Eric H. Holbrook and Donald A. Leopold

25 Immunology and Allergy 379
Mohamad Raafat Chaaban and Robert M. Naclerio

26 Allergy Testing 412
James W. Mims

27 Diagnostic Imaging 422
Jenny K. Hoang and Adam M. Becker

28 Diagnostic Tools for Sinonasal Disease and Role of Office Imaging 446
Luke Rudmik and Timothy L. Smith

29 Allergic Rhinitis 460
James T. O'Neil and James W. Mims

30 Nonallergic Rhinitis 469
Teresa V. Chan

31 Systemic Diseases that Affect the Nose and Sinuses 489
David A. Zopf and Mark A. Zacharek

32 Epistaxis 501
Benjamin S. Bleier and Rodney J. Schlosser

33 Acute Rhinosinusitis 509
Elizabeth K. Hoddeson and Sarah K. Wise

34 Chronic Rhinosinusitis with Nasal Polyposis 525
Matthew W. Ryan

35 Nonpolypoid Rhinosinusitis: Pathogenesis, Diagnosis, Staging, and Treatment 535
Zara M. Patel and Peter H. Hwang

36 The Unified Airway 550
Jeb M. Justice and Richard R. Orlandi

37 Fungal Rhinosinusitis 557
Robert T. Adelson, Bradley F. Marple, and Matthew W. Ryan

38 Complications of Rhinosinusitis 573
Carla M. Giannoni

39 Medical Management of Chronic Sinusitis 586
Jeffrey D. Suh and Alexander G. Chiu

40 Endoscopic Sinus Surgery for Chronic Rhinosinusitis 595
Barry M. Schaitkin and Kenneth D. Rodriguez

41 External Approaches in Sinus Surgery 604
Carlos D. Pinheiro-Neto and Carl H. Snyderman

42 Septoplasty, Turbinate Reduction, and Correction of Nasal Obstruction 612
Neal C. Gehani and Steven M. Houser

43 Endoscopic Orbital and Lacrimal Surgery 622
Erik Kent Weitzel and Raymond I. Cho

44 Complications of Sinus Surgery 638
James A. Stankiewicz and Kevin C. Welch

45 Endoscopic Evaluation and Treatment of CSF Leaks 662
Pete S. Batra

46 Frontal Sinus Surgery 675
Yuresh S. Naidoo and Peter-John Wormald

SECTION III: GENERAL OTOLARYNGOLOGY 689

47 Anatomy and Physiology of the Salivary Glands 691
Rohan R. Walvekar, Bridget C. Loehn, and Meghan N. Wilson

48 Nonneoplastic Diseases of the Salivary Glands 702
Rohan R. Walvekar and Matthew A. Bowen

49 Outcomes, Effectiveness, and Quality of Life: Measuring Clinical Effectiveness 717
Maureen Hannley

50 Taste 729
Natasha Mirza

51 Stomatitis 736
Richard O. Wein and Miriam O'Leary

52 Pharyngitis 757
Stephen R. Hoff and Kay W. Chang

53 Odontogenic Infections 770
Timothy D. Doerr

54 Management of Temporomandibular Joint Pain and Dysfunction 782
Joseph J. Fantuzzo and Sveta Karelsky

55 Deep Neck Infections 794
Behrad B. Aynehchi and Gady Har-El

SECTION IV: LARYNGOLOGY 815

56 Upper Digestive Tract Anatomy and Physiology 817
Libby J. Smith and Roxann Diez Gross

57 Functional Assessment of Swallowing 825
Maggie A. Kuhn and Peter C. Belafsky

58 Nonsurgical Management of Swallowing Disorders 838
Shaum S. Sridharan, Cathy L. Lazarus, and Milan R. Amin

59 Esophageal Disorders 852
Catherine Rees Lintzenich

60 Management of Intractable Aspiration 859
David E. Eibling

61 Upper Airway Anatomy and Function 868
Gayle E. Woodson

62 Upper Airway Stenosis: Evaluation and Management 879
Philip A. Weissbrod and Albert L. Merati

63 Complex Upper Airway Problems 896
Jay B. Tuchman and Deepak K. Mehta

64 Advanced Airway Management—Intubation and Tracheotomy 908
Karen M. Kost

65 Voice: Anatomy, Physiology, and Clinical Evaluation 945
Lucian Sulica

66 Laryngopharyngeal Reflux 958
Joel H. Blumin and Nikki Johnston

67 Infection, Infiltration, and Benign Neoplasms of the Larynx 978
Craig R. Villari and Melissa M. Statham

68 Benign Vocal Fold Lesions and Phonomicrosurgery 989
John W. Ingle and Clark A. Rosen

69 Treatment of Vocal Fold Paralysis 1004
VyVy N. Young and C. Blake Simpson

70 Neurologic Disorders of the Larynx 1026
John P. Ney and Tanya K. Meyer

71 Voice Therapy for the Treatment of Voice Disorders 1048
Jackie Gartner-Schmidt

72 Care of the Professional Voice 1059
Julina Ongkasuwan and Mark S. Courey

73 Office-Based Procedures in Laryngology 1078
Manish D. Shah and Michael M. Johns III

SECTION V: TRAUMA 1091

74 Principles of Trauma 1093
Peter J. Koltai and James Chan

75 Management of Soft Tissue Injuries of the Face 1108
Scott Shadfar and William W. Shockley

76 Penetrating Face and Neck Trauma 1131
Michael G. Stewart

77 Laryngeal Trauma 1141
J. Randall Jordan, Byron K. Norris, and Scott P. Stringer

78 Principles in Rigid Fixation of the Facial Skeleton 1153
Robert M. Kellman and Sherard A. Tatum

79 Surgical Approaches to the Craniofacial Skeleton 1171
John F. Hoffmann

80 Mandibular Fractures 1195
Brett A. Miles and Jesse E. Smith

81 Midface Fractures 1209
Brendan C. Stack Jr., and Francis P. Ruggiero

82 Orbital Fractures 1225
Clinton D. Humphrey and J. David Kriet

83 Nasal Fractures 1241
Grant S. Gillman and Carlos M. Rivera-Serrano

84 Frontal Sinus Fractures 1255
E. Bradley Strong

85 Pediatric Facial Fractures 1272
Peter C. Revenaugh and Paul Krakovitz

SECTION VI: PEDIATRIC OTOLARYNGOLOGY 1285

86 Pediatric Otolaryngology 1287
Stephen C. Maturo and Michael Cunningham

87 Congenital Aerodigestive Tract Anomalies 1306
Christopher T. Wootten and Charles M. Myer III

88 Neonatal Respiratory Distress 1328
Mark Boston

89 Stridor, Aspiration, and Cough 1338
Joseph E. Dohar and Samantha Anne

90 Laryngeal Stenosis 1356
Michael J. Rutter, Aliza P. Cohen, and Alessandro de Alarcón

91 Pediatric Voice 1372
Susan Baker Brehm, Melissa M. Statham, and Alessandro de Alarcón

92 Pediatric Tracheotomy 1382
Jeffrey P. Simons

93 Ingestion Injuries and Foreign Bodies in the Aerodigestive Tract 1399
Warren K. Yunker and Ellen M. Friedman

94 Recurrent Respiratory Papillomatosis 1409
Craig S. Derkay and Cristina M. Baldassari

95 Adenotonsillar Disease in Children 1430
Anita Jeyakumar, Sean Miller, and Ron B. Mitchell

96 Congenital Anomalies of the Nose 1445
John P. Bent and David E. Conrad

97 Pediatric Rhinosinusitis 1455
Rodney P. Lusk

98 Salivary Gland Disease in Children 1467
Matthew K. Whitley and Karen B. Zur

99 Otitis Media in the Age of Antimicrobial Resistance 1479
Margaretha L. Casselbrant and Ellen M. Mandel

100 Pediatric Audiology and Implantable Hearing Devices 1507
David H. Chi and Diane L. Sabo

101 Nongenetic Hearing Loss 1523
Margaret A. Kenna

102 Genetic Hearing Loss 1541
John Greinwald and Catherine Hart

103 Comprehensive Cleft Care 1556
Alexander J. Davit III, Todd Otteson, and Joseph E. Losee

104 Congenital Vascular Lesions 1574
Ravindhra G. Elluru

105 Head and Neck Masses in Children 1589
Cuneyt M. Alper and Jacob G. Robison

106 Congenital Cysts and Sinuses of the Head and Neck 1607
Robert F. Yellon

107 The Syndromal Child 1617
Ted L. Tewfik

VOLUME TWO

SECTION VII: HEAD AND NECK SURGERY 1643

108 Head and Neck Tumor Biology 1645
Alec Vaezi and Jennifer R. Grandis

109 Principles of Patient Care 1672
Rohan R. Walvekar, Marcie C. Tauzin, and Neelima Tammareddi

110 Principles of Radiation Oncology 1682
Umamaheswar Duvvuri and Gregory J. Kubicek

111 Chemoradiation 1692
Christine G. Gourin and Arlene A. Forastiere

112 Therapeutic Options for Patients Who Fail Primary Chemoradiation 1708
Steven B. Cannady and Mark K. Wax

113 Cutaneous Malignancy 1723
Cherie-Ann O. Nathan and Timothy S. Lian

114 Malignant Melanoma of the Head and Neck Region 1739
Aaron J. Berger, Jeffrey N. Myers, Andrew J. Nemechek, and Mike Yao

115 Salivary Gland Neoplasms 1760
Young S. Oh, Matthew S. Russell, and David W. Eisele

116 Lip Cancer 1788
Liana Puscas, Michael A. Fritz, and Ramon M. Esclamado

117 Neck Dissection 1807
Jesus E. Medina and Nilesh R. Vasan

118 Controversies in Management of the N0 Neck in Squamous Cell Carcinoma of the Upper Aerodigestive Tract 1839
Ryan Case and Karen T. Pitman

119 Oral Cavity Cancer 1849
Daniel G. Deschler and Audrey B. Erman

120 Nasopharyngeal Carcinoma 1875
William Ignace Wei and Daniel T. T. Chua

121 Oropharyngeal Cancer 1898
Anna M. Pou and Jonas T. Johnson

122 Hypopharyngeal and Cervical Esophageal Carcinoma 1917
Mihir Kiran Bhayani and Randal S. Weber

123 Early Laryngeal Cancer 1940
Parul Sinha, Oluwafunmilola Okuyemi, and Bruce H. Haughey

124 Advanced Laryngeal Cancer 1961
Bridget C. Loehn, Melda Kunduk, and Andrew J. McWhorter

125 Voice Rehabilitation Following Laryngectomy 1978
Anna M. Pou

126 Tracheal Tumors 1990
Kevin L. Potts and Jeffrey M. Bumpous

127 Vascular Tumors of the Head and Neck 1999
Mark Persky and Spiros Manolidis

128 Lymphomas of the Head and Neck 2032
Raymond L. Chai, Andrew B. Tassler, and Seungwon Kim

129 Neoplasms of the Nose and Paranasal Sinuses 2044
Lee A. Zimmer and Ricardo L. Carrau

130 Orbital Tumors 2063
Neda Esmaili, Michael E. Stadler, and Adam M. Zanation

131 Cranial Base Surgery 2081
Carlos D. Pinheiro-Neto, Carl H. Snyderman, and Paul A. Gardner

132 Odontogenic Cysts, Tumors, and Related Jaw Lesions 2097
William L. Chung, Kurt F. Summersgill, and Mark W. Ochs

133 Treatment of Thyroid Neoplasms 2115
Irene Zhang, Samantha DeMauro-Jablonski, and Robert L. Ferris

134 Hyperparathyroidism: Evaluation and Surgery 2131
Maisie L. Shindo

SECTION VIII: SLEEP MEDICINE 2147

135 **Sleep Medicine for the Otolaryngologist 2149**
Pell Ann Wardrop and Kathleen L. Yaremchuk

136 **Medical Therapy for Obstructive Sleep Apnea 2174**
Ryan J. Soose and Patrick J. Strollo

137 **Nasal and Palatal Surgery for OSA 2191**
Peter D. O'Connor and Tucker Woodson

138 **Hypopharyngeal and Skeletal Surgery for OSA 2206**
Eric James Kezirian and Edward M. Weaver

139 **Pediatric Sleep-Disordered Breathing 2220**
Stacey L. Ishman, David F. Smith, and Sally R. Shott

SECTION IX: OTOLOGY 2237

140 **Development of the Ear 2239**
Michael John Wareing, Anil K. Lalwani, Abbas A. Anwar, and Robert K. Jackler

141 **Anatomy and Physiology of Hearing 2253**
Peter C. Weber and Samir Khariwala

142 **Assessment of Peripheral and Central Auditory Function 2274**
James W. Hall III and Patrick J. Antonelli

143 **Vestibular Function and Anatomy 2291**
J. Christopher Holt and Shawn D. Newlands

144 **Vestibular and Balance Laboratory Studies 2302**
Neil T. Shepard, Kristen L. Janky, and Jaynee A. Handelsman

145 **Neurophysiologic Intraoperative Monitoring 2314**
Brannon D. Mangus, Betty S. Tsai, and David S. Haynes

146 **Diseases of the External Ear 2333**
Christopher J. Linstrom and Frank E. Lucente

147 **Neoplasms of the Ear and Lateral Skull Base 2358**
Bradley P. Pickett and Brianna K. Crawley

148 **Congenital Malformation of the Ear 2384**
Paul R. Lambert

149 **Intratemporal and Intracranial Complications of Otitis Media 2399**
H. Alexander Arts and Meredith E. Adams

150 **Middle Ear and Temporal Bone Trauma 2410**
Rodney C. Diaz, Sally M. Kamal, and Hilary A. Brodie

151 **Cholesteatoma 2433**
Ted A. Meyer, Chester L. Strunk Jr., and Paul R. Lambert

152 **Surgery of the Mastoid and Petrosa 2447**
Richard A. Chole, Hilary A. Brodie, and Abraham Jacob

153 **Reconstruction of the Tympanic Membrane and Ossicular Chain 2465**
John L. Dornhoffer and Michael B. Gluth

154 **Otosclerosis 2487**
Brandon Isaacson, Joe Walter Kutz Jr., and Peter S. Roland

155 **Acute Paralysis of the Facial Nerve 2503**
Jeffrey T. Vrabec and Jerry W. Lin

156 **Otologic Manifestations of Systemic Disease: Includes Autoimmune Inner Ear Disease 2519**
Arnaud F. Bewley and Michael J. Ruckenstein

157 **Noise-Induced Hearing Loss 2530**
Robert A. Dobie

158 **Ototoxicity 2542**
Kay W. Chang

159 **Cerebellopontine Angle Tumors 2556**
Matthew L. Bush and D. Bradley Welling

160 **Sudden Sensory Hearing Loss 2589**
Eric R. Oliver and George T. Hashisaki

161 **Tinnitus and Hyperacusis 2597**
Maura K. Cosetti and Pamela C. Roehm

162 **Aging and the Auditory and Vestibular System 2615**
Joe Walter Kutz Jr., Brandon Isaacson, and Peter S. Roland

163 **Cochlear Implants and Other Implantable Auditory Prostheses 2624**
Oliver F. Adunka and Craig A. Buchman

164 **Hearing Aids and Assistive Listening Devices 2654**
Catherine V. Palmer and Barry E. Hirsch

165 **Clinical Evaluation of the Patient with Vertigo 2673**
Courtney C. J. Voelker and Joel A. Goebel

166 **Peripheral Vestibular Disorders 2701**
Yuri Agrawal, Lloyd B. Minor, and John P. Carey

167 **Central Vestibular Disorders 2717**
Gail Ishiyama and Akira Ishiyama

168 **Vestibular Rehabilitation 2733**
Susan L. Whitney and Yael Raz

169 Regenerative Strategies for Overcoming Deafness 2747
Alan G. Cheng and Stefan Heller

SECTION X: FACIAL PLASTIC AND RECONSTRUCTIVE SURGERY 2755

170 Preoperative Evaluation and Facial Analysis in Facial Plastic Surgery 2757
Andrew Winkler and Justin M. Wudel

171 Pictorial Documentation: Digital Imaging and Traditional Photography 2772
Andrew K. Patel, Amir M. Karam, and Samuel M. Lam

172 Grafts and Implants in Facial, Head, and Neck Surgery 2784
G. Richard Holt and Christian L. Stallworth

173 Local Cutaneous Flaps and Grafts 2797
Brian Jewett

174 Reconstructive Microsurgery of the Head and Neck 2824
Douglas B. Chepeha

175 Tissue Expanders 2849
Jonathan Liang and Jonathan M. Sykes

176 Scar Camouflage 2859
Shawn M. Stevens and Krishna G. Patel

177 Nasal Reconstruction 2871
Stephen S. Park

178 Facial Reanimation 2905
Tessa A. Hadlock

179 Surgical Anatomy of the Nose: A Foundation for Rhinoplasty 2919
David W. Kim and Ted Mau

180 Rhinoplasty: Incisions, Approaches and Analysis 2941
Grant S. Gillman

181 The Nasal Dorsum: Management of the Upper Two-Thirds of the Nose 2952
Randolph B. Capone and Ira D. Papel

182 Nasal Tip Surgery 2964
Tatiana K. Dixon and Dean M. Toriumi

183 Management of the Crooked Nose 2977
Craig S. Murakami and Richard A. Zoumalan

184 Revision Rhinoplasty 2989
Richard E. Davis

185 The Aging Forehead 3053
Kian Karimi and Peter A. Adamson

186 Upper Eyelid Blepharoplasty 3074
Jonathan M. Sykes and Christina K. Magill

187 Lower Eyelid Blepharoplasty 3085
Stephen W. Perkins and Jess Prischmann

188 Rhytidectomy (Face-Lift) 3103
Russell W. H. Kridel and Zahi Abou Chacra

189 The Aging Neck 3131
Edwin Francis Williams and Henry Haipei Chen

190 Otoplasty: Anatomy, Embryology, and Technique 3142
Steven Ross Mobley and Nathan Todd Nelson Schreiber

191 Congenital Auricular Malformation 3161
Eugenio A. Aguilar III and Anthony Echo

192 Chin Augmentation 3176
Jonathan M. Sykes and Christina K. Magill

193 Redefining Skin Resurfacing: The Hetter Chemical Peel 3189
Devinder S. Mangat

194 Lasers in Facial Plastic Surgery 3200
William Russell Ries and Joseph E. Hall

195 Management of Benign Facial Lesions 3212
Karen J. Sundby, and John A. Zitelli

196 Management of Alopecia 3229
Raymond J. Konior and Steven Gabel

197 Cosmetic Uses of Neurotoxins and Injectable Fillers 3239
Grant S. Gillman

SECTION XI: CONTEMPORARY ISSUES IN MEDICAL PRACTICE 3253

198 Patient Safety 3255
David E. Eibling

199 Business Law and the Practice of Otolaryngology 3270
Robert S. Iwrey, Stephanie P. Ottenwess, Jessica L. Gustafson, Kathryn Hickner-Cruz, David M. Ottenwess, and Reginald Baugh

200 Compliant Documentation, Coding, and Billing in the Practice of Otolaryngology—Head and Neck Surgery 3303
Stephen R. Levinson

201 Clinic Management 3332
Dana E. Habers and Scott P. Stringer

202 Comparative Medical Systems 3341
William Anthony Wood

203 **Effective Education in Medical Practice** 3349
John M. Schweinfurth

204 **Medical Informatics and Databases** 3354
John C. Sok and Richard K. McHugh

205 **Telemedicine for Otolaryngology** 3361
John Kokesh, Chris Patricoski, and A. Stewart Ferguson

206 **Quality Improvement in Otolaryngology** 3372
Rahul K. Shah, Jean Brereton, and David W. Roberson

207 **Conflict of Interest** 3380
Andrew H. Murr and Susan J. Murr

FOREWORD

The editorial team of this fifth edition of *Head and Neck Surgery—Otolaryngology* is pleased to present you with the newest and most up-to-date version of the foremost textbook in *Head and Neck Surgery—Otolaryngology*. The fifth edition features a revised and more comprehensive table of contents authored by the thought leaders in our field focusing upon the modern practice of medicine.

This text is intended for use by students and practitioners at every level. The pace of the development of new material and information in the world of biomedical science has made information management a contemporary challenge. There is an increasing demand for the practice of evidence-based medicine. Clinical proficiency and mastery of the information are presented in a concise and clear manner in this text and will serve the practitioner in his/her preparation for the future.

The editorial team remains grateful for this opportunity to continue their pioneering efforts of Byron J. Bailey, MD, and the many section editors and authors who have contributed so much to making this the preeminent text of our field. Special thanks also goes to Jackie Lynch for her editorial assistance and a special acknowledgment of the detailed, meticulous artwork of Anthony Pazo.

Clark A. Rosen, MD
Jonas T. Johnson, MD

PREFACE

"More than a textbook—it's a learning system." That has been our challenging goal since the first edition of "*Head and Neck Surgery—Otolaryngology*" went to the printer 20 years ago. Once again, we began the planning of this fifth edition with the recruiting of experienced and expert authors capable of providing our readers with the most current and useful evidence-based information available for residents and practicing physicians intent on mastering the practice of our specialty.

Comprehensive, concise, and practical content that is presented in the format designed to increase the understanding, retention, and application of knowledge is the end result of the efforts of our outstanding team of Section Editors led by Jonas Johnson and Clark Rosen. Useful illustrations, helpful summary tables, and supplemental video segments enhance the effort of the learner to retain and apply the information contained in these volumes. A new and valuable study guide companion, *Bailey's Head and Neck Surgery: Otolaryngology Review*, will be published separately to assist with benchmarks of the progress that the reader has made.

And now, with sincere thanks to the authors and editors who have made this learning system possible, we have arrived once again at the point where vision becomes reality.

Many months of hard work have been transformed into a product with the potential to move clinical care to a higher level, and that is always the foundation of our striving.

We welcome our new readers and we applaud your decision to join us in this quest for greater understanding for ourselves and improved care for our patients.

Byron J. Bailey, MD, FACS
Chairman Emeritus, Department of Otolaryngology
The University of Texas Medical Branch
Galveston, Texas

Surgical Anatomy of the Head and Neck

1

Michael D. Maves

Anatomy is the basic science of all surgery. Surgery in the region of the head and neck cannot be considered safe unless the surgeon thoroughly understands the anatomy of this area and its important variations. Although anatomic structures and the relations between them do not change, our knowledge of anatomy must be continually updated to meet the challenge of new surgical techniques and approaches. This chapter is an overview of the surgical anatomy of the head and neck with a focus on the major regions. It is not a substitute for thorough anatomic knowledge, which can be gained only through intensive study in a cadaver laboratory and an operating room.

THE CRANIUM

Scalp

The cranium is covered by the hair-bearing scalp, which is divided into layers of skin and subcutaneous tissue, galea aponeurotica, loose connective tissue, and periosteum or pericranium covering the calvarial vault. The blood supply of the scalp comes from the paired supraorbital and supratrochlear arteries anteriorly, the terminal branches of the superficial temporal arteries laterally, and the occipital vessels posteriorly. This rich vascularity provides a network on which small scalp flaps can be based and rotated, as in the management of male pattern baldness. Sensation to the scalp is provided by branches of cranial and spinal nerves.

Calvaria

The bony vault of the cranium, the calvaria, consists of the unpaired frontal bone, the paired parietal bones, and the unpaired occipital bone (Fig. 1.1). In the lateral aspect, the greater wing of the sphenoid bone and the temporal bone complete the cranium. There is a rich layer of diploic bone between the inner and outer tables of the calvaria. This is a source for split-thickness calvarial bone grafts, which often are used in head and neck reconstruction. The calvarium is thickest at the external occipital protuberance and in the parietal region. It is thinnest over the temporal region. This allows ready access for neurotologic operations on the middle fossa. The venous circulation of the calvaria is provided by diploic veins, which drain to the veins of the scalp or into the dural venous sinuses. In some instances, the diploic veins are connected to each other, and this communication allows osteomyelitis that originates in the frontal sinus to involve the frontal bone, scalp, and dura.

CRANIAL FOSSAE

The intracranial cavity is roughly divided into three fossae. The anterior or frontal cranial fossa contains the paired frontal lobes and provides access to the nasal cavity for the olfactory nerves through the cribriform plate. The crista galli provides superior midline extension of the nasal septum. The middle cranial fossa contains the temporal lobes. In this important junction of the cranial cavity, the middle meningeal artery arises from the foramen spinosum, and the trigeminal nerve enters through the superior orbital fissure (V1), the foramen rotundum (V2), and the foramen ovale (V3). Cranial nerves II, III, IV, and VI, which traverse the cavernous sinus and enter the orbit, also course through the middle cranial fossa. The internal carotid artery is in its place in the carotid siphon as it traverses the cavernous sinus in this region. The posterior cranial fossa contains the paired cerebellar hemispheres and the brainstem. In this location, the internal auditory meatus is associated with the seventh and eighth cranial nerve complex. The jugular foramen, transverse sinus, and foramen magnum are the major landmarks of the posterior cranial fossa.

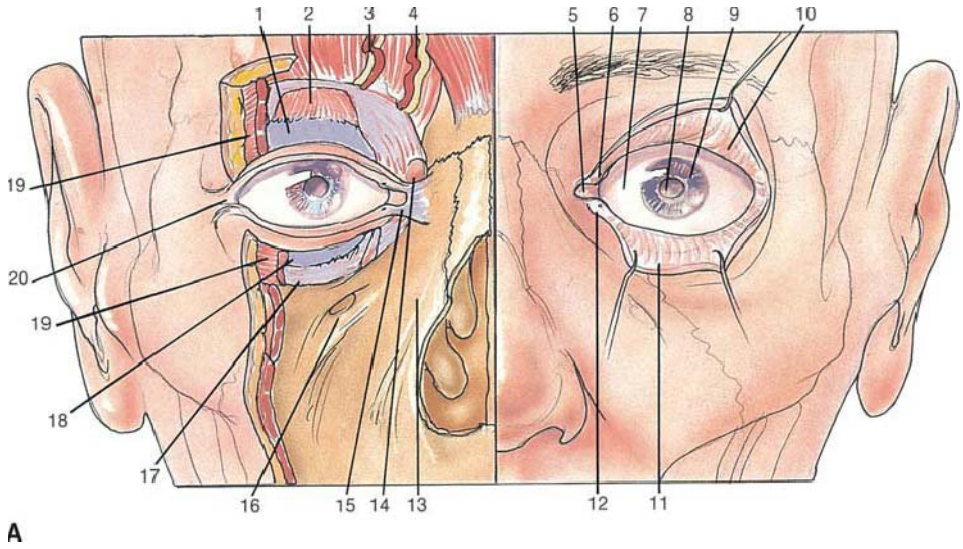
EYELID, ORBIT, AND EYE

Eyelids



The upper and lower eyelids are similar in structure, although the upper eyelid is more mobile and has features not found in the lower eyelid. The space between the eyelids is known as the palpebral fissure, which is limited medially and laterally by the canthi. At the medial canthus is the lacrimal caruncle, where there is a small lake of tears and the tiny papillae of the lacrimal duct system. The conjunctiva is a thin mucous membrane layer that covers the inner aspects of the eyelids and extends onto the surface of the globe.

Tarsus

The upper tarsal plate provides rigidity to the upper eyelid and is larger than the lower tarsus (Fig. 1.2). Each eyelid consists (from without inward) of skin, subcutaneous tissue, voluntary muscle of the orbicularis oculi, orbital septum, tarsus, smooth muscle, and conjunctiva. The more freely mobile upper lid receives the insertion of the levator palpebrae superioris muscle. The orbicularis oculi is the sphincteric muscle of the upper and lower eyelids. It attaches at a medial palpebral ligament and spreads in an arc laterally and inferiorly to provide a sphincteric muscle to the eye. It receives innervation from the temporal and zygomatic branches of the facial nerve. This muscle interdigitates with the frontalis muscle and the corrugator supercilii.

Blood Supply

The arterial supply of the eyelids is provided by the angular branch of the facial artery, which forms an anastomotic network with the supraorbital and supratrochlear artery and shares a small contribution from the superficial temporal vessels. The veins of the eyelids are larger and more numerous than the arteries and drain into the ophthalmic and angular veins medially and the superficial temporal vein laterally. Accompanying the peripheral arterial arcade of the upper eyelid, the veins of the small venous plexus drain into the ophthalmic vein, which drains posteriorly to the cavernous sinus. The veins in this region of the face do

not have valves and may propagate septic emboli posteriorly. This is a particularly dangerous situation for patients who have infections in the areas of the eyelids or periorbital abscess. These patients are at risk of cavernous sinus thrombosis.

Lacrimal System

The lacrimal apparatus consists of a secretory portion, the lacrimal gland, its ducts, the drainage apparatus, the lacrimal canaliculi and sac, and the nasolacrimal duct (Fig. 1.3). The lacrimal gland is partially divided into two portions by the lateral horn of the aponeurosis of the levator palpebrae. The larger orbital portion of the gland lies in a shallow fossa on the frontal bone and is in contact anteriorly with the orbital septum. The excretory ductules of the lacrimal gland run through the orbital part of the gland, run through or close to the posterior part of the palpebral portion, and are joined by ducts from this portion.

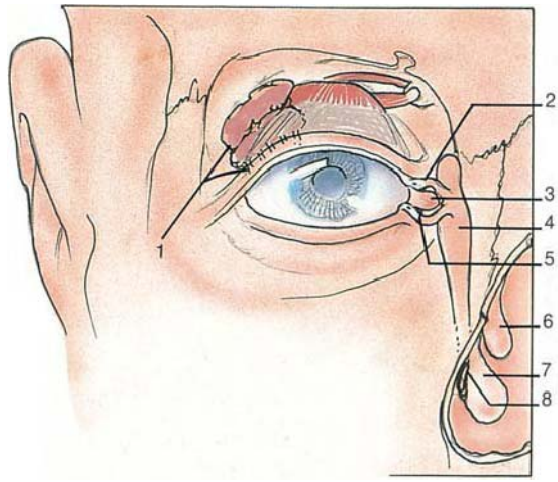

Figure 1.3 Lacrimal apparatus and drainage system. *1*, Lacrimal gland and ducts; *2*, superior lacrimal papilla and puncta; *3*, lacrimal caruncle; *4*, lacrimal sac; *5*, inferior lacrimal papilla and puncta; *6*, middle nasal concha; *7*, inferior nasal concha; *8*, opening of nasolacrimal duct.

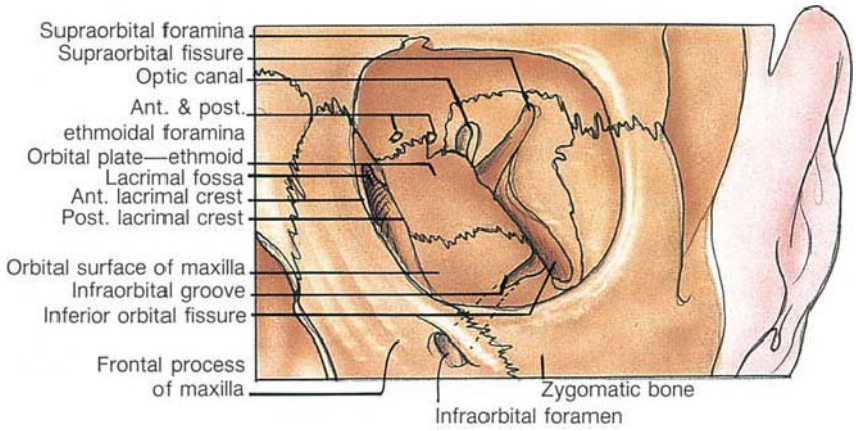

Figure 1.4 Bony orbit.

Removal of the palpebral portion can destroy the drainage of the entire gland.

Movement of the eyelid distributes tears over the surface of the eye, and any excess tends to accumulate in the lacrimal lake. This structure drains into the paired superior and inferior canaliculi and from there into the lacrimal sac. The lacrimal sac is housed in the bony lacrimal fossa of the medial orbital wall. This drains into the nasal lacrimal duct and eventually into the inferior meatus of the nose.

Orbit

The bony orbit consists of the medial wall occupied largely by the ethmoid bone, lacrimal bone, and a portion of the nasal process of the maxilla (Fig. 1.4). The floor of the orbit consists of the roof of the maxilla. The inferior orbital fissure is at its lateral extent. The zygomatic bone and greater wing of the sphenoid form the lateral orbital wall and join the frontal bone superiorly to complete the pyramidal bony orbit. On its medial aspect are the paired ethmoidal foramina, which provide a route to the orbit for the anterior and posterior ethmoidal arteries. The optic canal posteriorly transmits the optic nerve and ophthalmic artery. The superior orbital fissure transmits cranial nerves III, IV, V, and VI and provides an aperture for the ophthalmic vein.

Eye

The eye consists of the cornea and sclera in the anterior aspect. The anterior chamber protrudes as a second sphere on the structure of the orbit. The lens and iris form the posterior portion of the anterior chamber. Contained within the substance of the eye is the vitreous. The retina rests on the choroid. The fovea centralis is the focal point of the eye. Asymmetric to the structure of the orbit is the insertion of the optic nerve and ciliary arteries.

The seven voluntary muscles of the orbit are the levator palpebrae superioris; the superior, inferior, medial, and lateral rectus muscles; and the superior and inferior oblique muscles (Fig. 1.5). The smooth muscles of the orbit are the orbitalis muscle, the superior and inferior tarsal muscles, and ciliary and iridial muscles within the eye. The superior oblique is supplied by cranial nerve IV, the lateral rectus

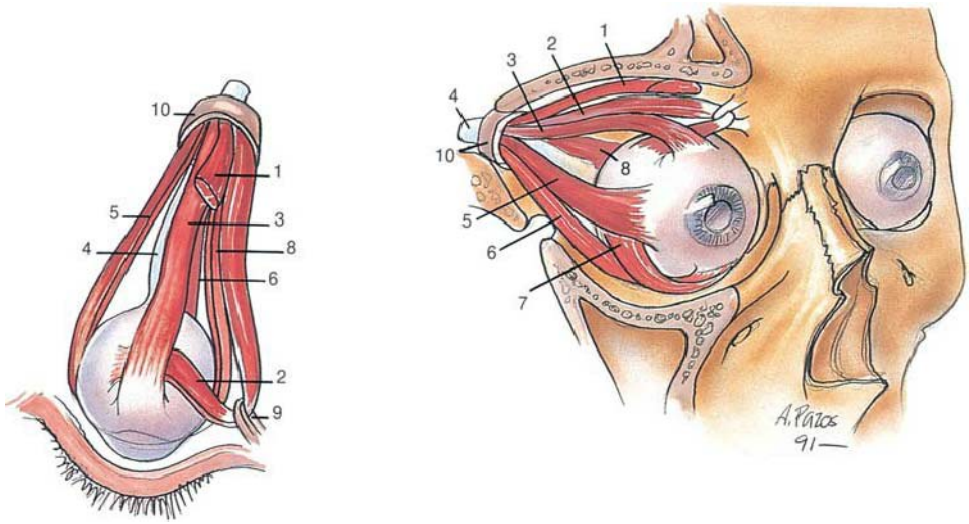

Figure 1.5 Eye muscles. *1*, Levator palpebrae superioris muscle; *2*, superior oblique muscle; *3*, superior rectus muscle; *4*, optic nerve; *5*, lateral rectus muscle; *6*, inferior rectus muscle; *7*, inferior oblique muscle; *8*, medial rectus muscle; *9*, trochlea; *10*, annular tendon.

is supplied by cranial nerve VI, and the other voluntary muscles of the orbit are supplied by cranial nerve III. The tarsal and orbital muscles (of Müller) are supplied by sympathetic fibers derived from the carotid plexus and from the superior cervical ganglion. The dilator pupillae, the sphincter pupillae, and the ciliary muscle are supplied by parasympathetic fibers through the oculomotor nerve (III).

The primary blood supply to the orbit is through the ophthalmic artery. The primary drainage is through the ophthalmic vein, which drains directly into the cavernous sinus. An additional anastomotic network is present on the anterior aspect of the face in the form of an arcade of vessels around the eyelids and through the pterygoid plexus.

THE EAR

The development and the anatomic and physiologic features of the ear are discussed in Chapters 140 and 141.

NOSE AND PARANASAL SINUSES

External Nose

The external part of the nose is a roughly pyramidal shape. The skeleton of the external nose is partly bony and partly cartilaginous and membranous. The nasal bones, which are usually narrow and thicker above, wider and thinner below, articulate firmly above with the nasal part of the frontal bone and with each other laterally with the nasal process of the maxilla (Fig. 1.6). Attached to the inferior aspect of the nasal bones are the upper lateral cartilages. These are continuous with the cartilaginous septum. In the inferior aspect, the lobule of the nose is formed mostly by the lower lateral cartilages, which consist of a medial and lateral crus. There are several small cartilages within the nasal ala. The chief arterial supply of the nose is from the facial artery through the angular artery and superior labial arteries. Venous drainage is similar, with a component gaining access to the ophthalmic vein through draining vessels from the trochlear and angular veins.

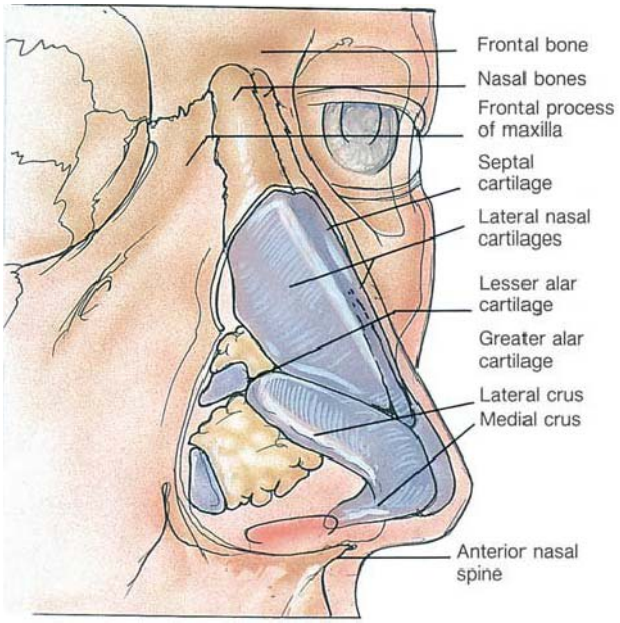

Figure 1.6 Bony and cartilaginous anatomic configuration of the external nose.

Nasal Cavity

The nasal cavities are also known as the *nasal fossae*. The nasal septum consists of the nasal septal cartilage, the nasal crest of the maxilla, the nasal crest of the palatine bone, the vomer, and the perpendicular plate of the ethmoid bone. The lateral nasal wall is formed by the prominent nasal turbinates. The meatus are situated below the corresponding turbinates (Fig. 1.7). The inferior meatus provides drainage

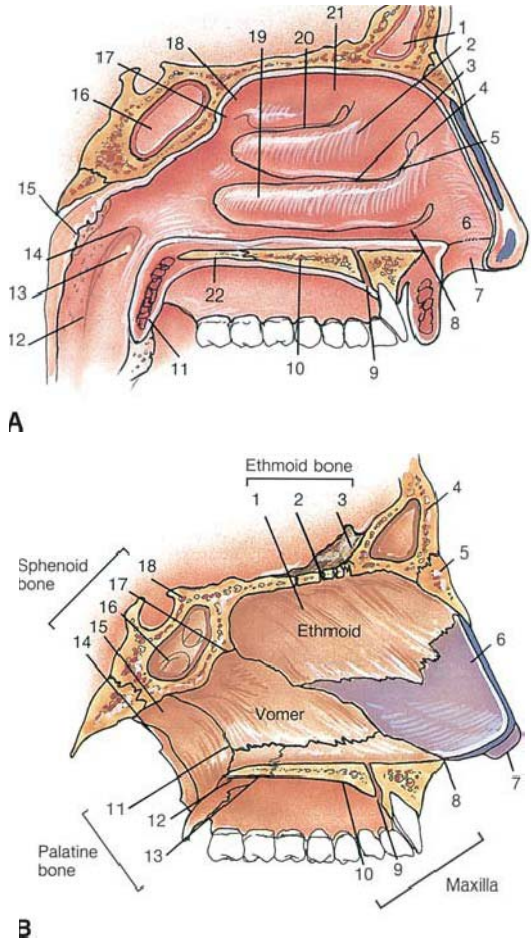

Figure 1.7 **A:** Lateral nasal wall. *1*, Frontal sinus; *2*, middle nasal concha; *3*, middle nasal meatus; *4*, agger nasi; *5*, atrium of middle nasal concha; *6*, limen; *7*, vestibule; *8*, inferior nasal meatus; *9*, incisive canal; *10*, palatine process of maxilla; *11*, soft palate; *12*, pharyngeal recess; *13*, eustachian tube orifice; *14*, torus tubarius; *15*, adenoid; *16*, sphenoid sinus; *17*, sphenoid sinus opening; *18*, sphenoethmoidal recess; *19*, inferior nasal concha; *20*, superior nasal meatus; *21*, superior nasal concha; *22*, palatine bone. **B:** Nasal septum. *1*, Perpendicular plate; *2*, cribriform plate; *3*, crista galli; *4*, frontal bone; *5*, nasal bone; *6*, septal cartilage; *7*, medial crus; *8*, anterior nasal spine; *9*, incisive canal; *10*, palatine process; *11*, perpendicular plate; *12*, postnasal spine; *13*, horizontal plate; *14*, lateral pterygoid plate; *15*, medial pterygoid plate; *16*, sphenoid sinus; *17*, crest; *18*, body.

for the nasolacrimal duct. The middle meatus provides drainage for the anterior nasal sinuses, namely the frontal sinus, anterior ethmoid sinuses, and the maxillary sinus. The superior meatus provides drainage for the posterior sinuses, namely the posterior ethmoid and sphenoid sinuses.

The arterial supply of this region is from internal carotid sources through the anterior and posterior ethmoid arteries and from an external carotid source through the sphenopalatine artery. Contributions also may exist from the greater palatine vessels and the septal branch of the superior labial artery. These form an important anastomotic network in the anterior septum known as the *Kiesselbach plexus*, which accounts for most nosebleeds.

Sinuses

The paranasal sinuses consist of the paired frontal, ethmoid, maxillary, and sphenoid sinuses (Fig. 1.8). The frontal sinus develops as one of several outgrowths from the region of the frontal recess. Two, three, or even more frontal sinuses on a side have been reported, and some persons have no frontal sinus. The degree of pneumatization of the frontal sinuses varies. Pneumatization may extend into the roof of the orbit and laterally into the frontal bone as far as the sphenoid wing. The frontal sinuses drain into the anterior aspect of the middle meatus.

Ethmoid Sinuses

The ethmoid sinuses consist of a variable number of separate cavities that honeycomb the ethmoid bone between the upper part of the lateral nasal wall and the medial wall of the orbit. The anterior ethmoid cells are divided into frontal recess cells, which open into the frontal recess of the middle meatus; infundibular cells, which open into the ethmoid infundibulum; and bullar or middle ethmoid cells, which open directly into the middle meatus on or above the ethmoid bulla. There may be one to seven posterior ethmoid cells. The bullae and posterior ethmoid cells may encroach on each other and overlap, the bullar cells spreading backward or the posterior cells spreading forward. The posterior ethmoid cells drain into the superior meatus.

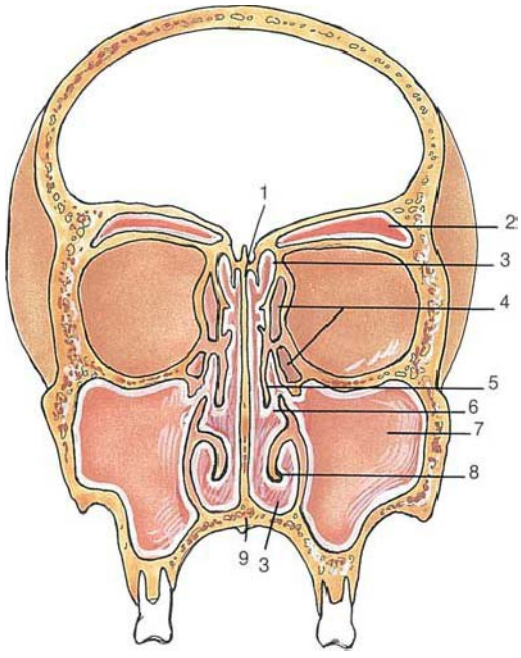

Figure 1.8 Paranasal sinuses. *1*, Nasal septum; *2*, frontal sinus; *3*, nasal cavities; *4*, ethmoidal cells; *5*, middle nasal concha; *6*, middle nasal meatus; *7*, maxillary sinus; *8*, inferior nasal concha; *9*, hard palate.

Sphenoid Sinus

The sphenoid sinus usually opens into the sphenoethmoidal recess above and behind the superior nasal concha. The ostium usually is in the posterior wall of the recess, but sometimes it is on its lateral wall. The degree of pneumatization of the sphenoid sinus varies. This variation is an important factor in surgical approaches to the pituitary gland. The relations of the sphenoid sinus are important because of the surrounding anatomic structures. The optic nerves are superior to the sinus, and the internal carotid artery is lateral to the sinus within the cavernous sinus. The maxillary nerve lies in the inferior lateral portion of the sinus in the anterior aspect. The hypophysis lies within the posterior superior portion of the sphenoid sinus and can be approached through transsphenoidal hypophysectomy.

Maxillary Sinus

The maxillary sinus usually is the largest of the paranasal sinuses and is situated in the body of the maxilla. Its anterior wall is the facial surface of this bone, and its posterior wall is the infratemporal surface. Its medial wall is that of the nasal cavity. The roof of the maxillary sinus is also the floor of the orbit, and it also may be affected in blow-out fractures of the orbit. The maxillary sinus drains into the middle meatus of the nasal cavity. The roots of the posterior molar teeth may extend into the sinus. The maxillary sinus is bounded posteriorly by the pterygomaxillary fossa, through which course the terminal branches of the internal maxillary artery. These vessels can be approached through the maxillary sinus for relief of epistaxis.

THE FACE

Facial Bones and Muscles

The bones of the face include the frontal and nasal bones and the facial bones proper—maxilla, mandible, zygomatic, and palatine bones. The facial and mimetic muscles are divided into five chief groups concerned with the mouth, nose, orbit, ear, and scalp (Fig. 1.9). The platysma muscle in the neck also belongs to the facial group. The chief action of these muscles is on skin into which they insert. All these muscles are innervated by the facial nerve.

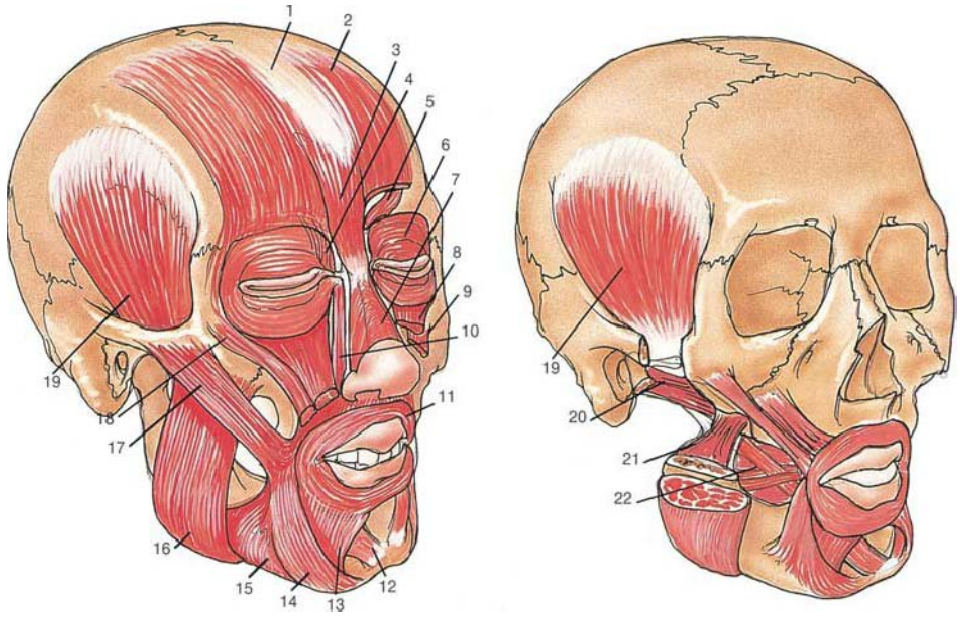

Figure 1.9 Facial muscles. *1*, Galea aponeurotica; *2*, frontalis; *3*, procerus; *4*, depressor supercilii; *5*, corrugator supercilii; *6*, orbicularis oculi; *7*, nasalis; *8*, levator labii superioris; *9*, levator anguli oris; *10*, levator labii superioris alaeque nasi; *11*, orbicularis oris; *12*, mentalis; *13*, depressor labii inferioris; *14*, depressor anguli oris; *15*, platysma; *16*, masseter; *17*, zygomaticus major; *18*, zygomaticus minor; *19*, temporalis; *20*, lateral pterygoid; *21*, medial pterygoid; *22*, buccinator.

Parotid Gland

The parotid gland, which is anterior to and below the lower part of the ear, extends subcutaneously backward over the anterior portion of the sternocleidomastoid muscle, forward over the masseter muscle, and deeply behind the ramus of the mandible to lie between the mandible and the external acoustic meatus and mastoid process (Fig. 1.10). The gland is roughly divided into a lateral and medial portion by the course of the facial nerve. Related to the parotid gland are several periparotid and intraparotid lymph nodes, which may swell. The parotid gland drains through the parotid duct. It is innervated by the auriculotemporal nerve from the otic ganglion.

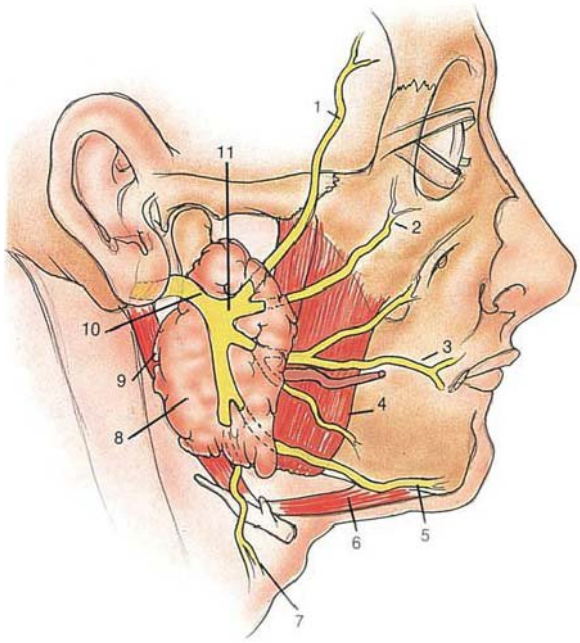

Figure 1.10 Parotid gland and facial nerve. *1*, Temporal branch; *2*, zygomatic branch; *3*, buccal branch; *4*, masseter muscle; *5*, marginal mandibular branch; *6*, anterior digastric muscle; *7*, cervical branch; *8*, parotid gland; *9*, posterior digastric muscle; *10*, seventh cranial or facial nerve; *11*, pes anserinus.

Facial Nerve

The anatomic characteristics of the facial nerve vary in the extracranial portion of the nerve. Identification of the nerve depends on marking the position of the posterior belly of the digastric muscle, the external meatal cartilage, the tympanomastoid suture line, and the styloid process.

ORAL STRUCTURES

Maxilla

The maxilla is the chief component of the upper jaw (Fig. 1.11). In addition to housing the dental apparatus and the maxillary sinus, it is related posteriorly to the medial and lateral pterygoid plates. The hard palate unites the paired maxilla and forms the bony roof of the oral cavity. Sensation to the upper teeth is provided by the maxillary nerve through the posterior superior and anterior superior alveolar nerves. The infraorbital nerve, another branch of V2, provides sensation over the face of the maxilla and soft tissues.

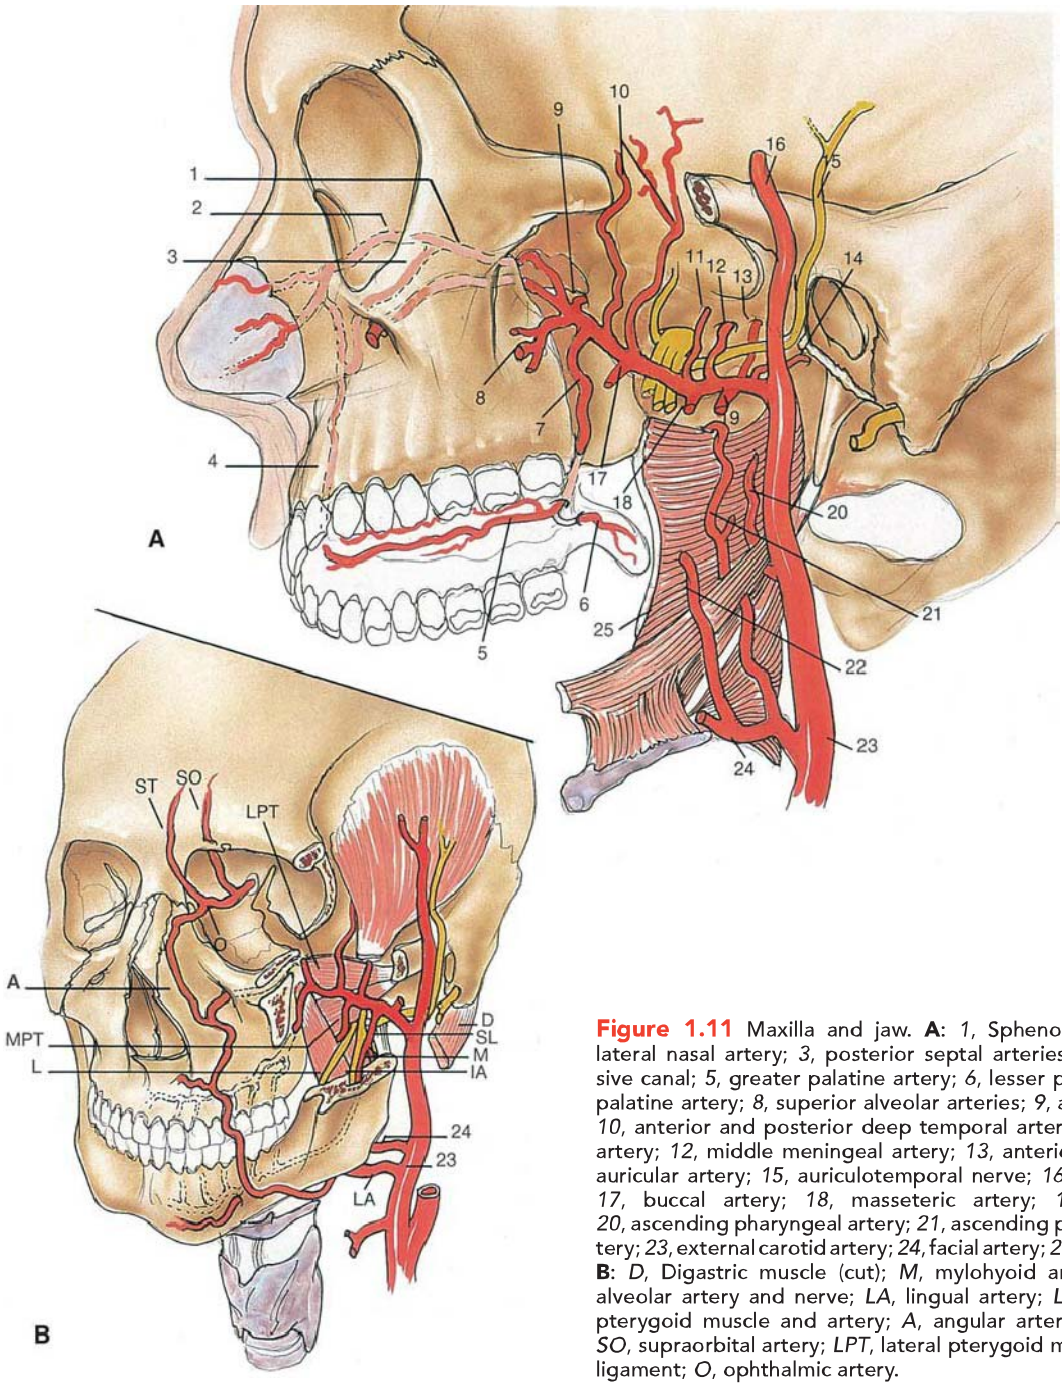

Figure 1.11 Maxilla and jaw. **A**: *1*, Sphenopalatine artery; *2*, posterior lateral nasal artery; *3*, posterior septal arteries; *4*, anastomosis in the incisive canal; *5*, greater palatine artery; *6*, lesser palatine artery; *7*, descending palatine artery; *8*, superior alveolar arteries; *9*, artery of the pterygoid canal; *10*, anterior and posterior deep temporal arteries; *11*, accessory meningeal artery; *12*, middle meningeal artery; *13*, anterior tympanic artery; *14*, deep auricular artery; *15*, auriculotemporal nerve; *16*, superficial temporal artery; *17*, buccal artery; *18*, masseteric artery; *19*, inferior alveolar artery; *20*, ascending pharyngeal artery; *21*, ascending palatine artery; *22*, tonsillar artery; *23*, external carotid artery; *24*, facial artery; *25*, superior constrictor muscle. **B**: *D*, Digastric muscle (cut); *M*, mylohyoid artery and nerve; *IA*, inferior alveolar artery and nerve; *LA*, lingual artery; *L*, lingual nerve; *MPT*, medial pterygoid muscle and artery; *A*, angular artery; *ST*, supratrochlear artery; *SO*, supraorbital artery; *LPT*, lateral pterygoid muscle; *SL*, sphenomandibular ligament; *O*, ophthalmic artery.

Palate

The palate intervenes between the nasal and oral cavities (Fig. 1.12). It consists of the maxilla, the horizontal process of the palatine bone, and the pterygoid plates. Soft tissues covering this area form the hard and soft palates of the roof of the mouth. The skeletal core of the soft palate is the palatine aponeurosis. The most superficial muscle fibers on the pharyngeal surface of the soft palate are those of the palatopharyngeus muscle. The levator veli palatini, tensor veli palatini, and uvular muscle complete the structures of the soft palate.

Mandible

The mandible, or lower jaw, consists of the tooth-bearing body and the ramus that extends upward from the angle of the mandible. The ramus, including the angle, is covered externally by the masseter muscle, which is crossed by the facial nerve and parotid duct. Between the ramus and the medial pterygoid muscle are the inferior alveolar and lingual nerves. Overlapping the posterior border of the ramus is the parotid gland, and within and paralleling this border is the upper portion of the external carotid artery. The superficial branch of this artery emerges from

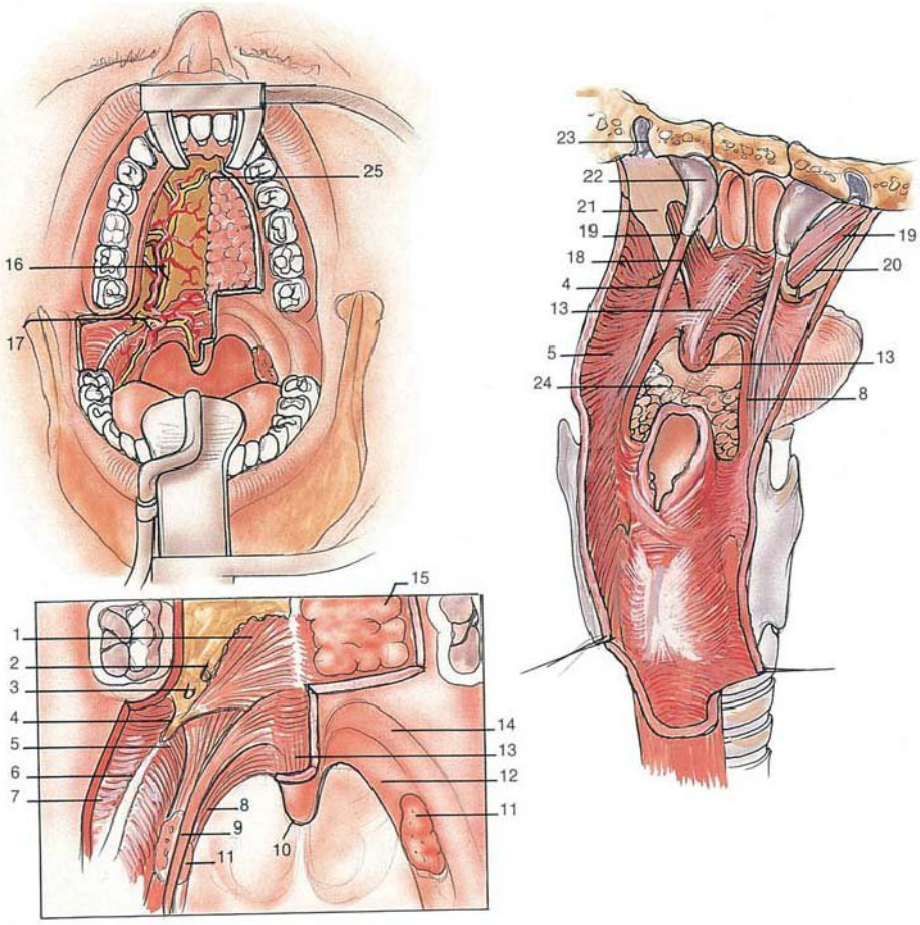

Figure 1.12 Palate. *1*, Veli palati muscles; *2*, greater palatine foramina; *3*, lesser palatine foramina; *4*, pterygoid hamulus; *5*, superior pharyngeal constrictor muscle; *6*, pterygomandibular raphe; *7*, buccinator muscle; *8*, palatopharyngeus muscle; *9*, palatoglossus muscle; *10*, uvula; *11*, palatine tonsil; *12*, palatopharyngeal arch; *13*, uvular muscle; *14*, palatoglossal arch; *15*, palatine glands; *16*, greater palatine artery and nerve; *17*, lesser palatine artery and nerve; *18*, salpingopharyngeus muscle; *19*, levator veli palatini muscle; *20*, tensor veli palati muscle; *21*, pharyngobasilar fascia; *22*, cartilaginous auditory tube; *23*, carotid canal; *24*, vallate papillae; *25*, incisive foramen.

the parotid gland behind the temporomandibular joint, and its internal maxillary branch runs transversely deep to the ramus. Inferiorly and medially, the angle and posterior part of the body of the mandible are related to the submandibular gland, and medially, the anterior part of the mandible is adjacent to the sublingual glands. The musculature most intimately concerned with the mandible and its movements consists of the masseter, temporal, and two pterygoid muscles (Fig. 1.9). These muscles govern mastication and are innervated by the third division of the trigeminal nerve.

Hyoid Bone and Tongue

The hyoid bone, to which are attached infrahyoid and suprahyoid muscles, effectively separates the anterior suprahyoid and infrahyoid fascial compartments. The suprahyoid muscles are the digastric and stylohyoid

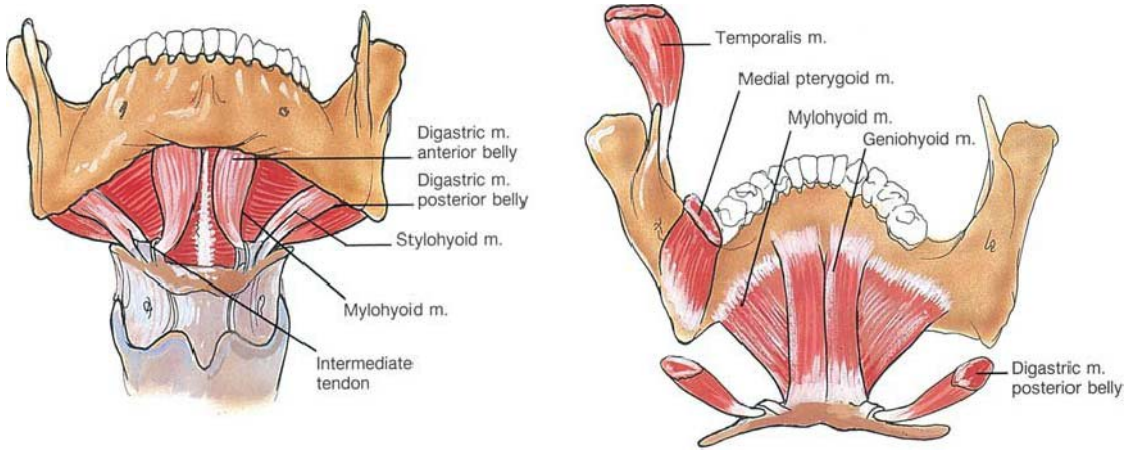

Figure 1.13 Suprahyoid muscles.

muscles, the mylohyoid and the geniohyoid muscles, and the muscles of the tongue (Fig. 1.13). The extrinsic muscles of the tongue are the genioglossus, the hyoglossus, and the styloglossus. The intrinsic muscles of the tongue are complicated bundles of interlacing fibers, among which are connective tissue septa. The midline septum lies between and effectively separates the muscles, nerves, and vessels of the two sides. It is an almost bloodless midline plane.

Submandibular Gland

The submandibular gland occupies most of the submandibular triangle and expands beyond this area over the superficial structures of the anterior and posterior bellies of the digastric muscle (Fig. 1.14). Its posterior border is close to the lower part of the parotid gland at the angle of the jaw, where it is separated from this gland by the stylomandibular ligament. The submandibular gland is crossed superficially by the facial vein and sometimes by the ramus mandibularis branch of the facial nerve. The larger submandibular lymph nodes lie along the superficial upper border of the gland, between it and the mandible. The anterior portion of the submandibular gland lies directly against the mylohyoid muscle and the mylohyoid nerve. Medial to the mandible and above the level of the submandibular gland is the lingual nerve in its course toward the tongue. When the submandibular gland is removed, the facial vein is sacrificed, but the ramus mandibularis branch of the facial nerve is preserved to avoid disruption of the corner of the mouth. The facial artery passes across the upper surface of the gland, usually grooving it deeply before rounding the lower border of the mandible, and must be sacrificed in removal of the gland. The submandibular and sublingual glands are innervated from the submaxillary ganglion fibers that accompany the sensory fibers of the lingual nerve. These fibers originate in the chorda tympani and pass into the submandibular ganglion.

PHARYNX AND LARYNX

The wall of the pharynx consists of mucosa and voluntary muscle. The mucosal structure of the pharynx varies. That of the nasal part is ciliated and resembles the mucosa of the nose. In the rest of the pharynx, the epithelium is stratified

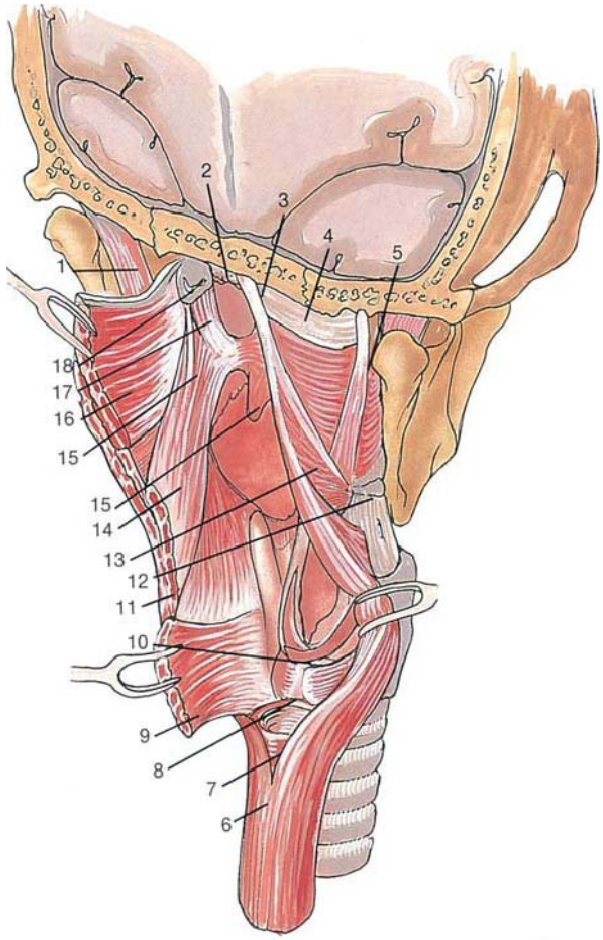

Figure 1.15 Pharynx. *1*, Digastric muscle, posterior belly; *2*, adenoid; *3*, pharyngeal raphe; *4*, pharyngobasilar fascia; *5*, stylopharyngeus muscle; *6*, longitudinal esophageal muscle; *7*, circular esophageal muscle; *8*, posterior cricoarytenoid muscle; *9*, cricopharyngeus muscle; *10*, transverse and oblique interarytenoid muscle; *11*, inferior constrictor muscle; *12*, hyoid bone; *13*, middle constrictor muscle; *14*, palatopharyngeus muscle; *15*, uvula; *16*, superior constrictor muscle; *17*, levator veli palati muscle; *18*, cartilaginous auditory tube. Please note that the posterior belly of the digastric muscle arises from the mastoid notch on the medial side of the base of the mastoid process.

squamous tissue. The muscular wall of the pharynx with its thin covering of buccal pharyngeal or visceral fascia is separated from the prevertebral fascia by an area of loose connective tissue that constitutes the retropharyngeal space.

Nasopharynx

The nasal part of the pharynx, the nasopharynx, is continuous anteriorly through the choanae with the nasal cavities (Fig. 1.15). The floor is the upper surface of the soft palate. The fornix or roof, the mucosa of which is attached close to the base of the skull, slopes downward and backward to become continuous with the posterior wall. The eustachian tubes are prominent on the lateral aspect of the nasal pharynx. There may be adenoid tissue in the superior recess of the nasopharynx.

Oropharynx

The oropharynx is continuous anteriorly through the fauces, or oral pharyngeal isthmus, with the oral cavity. The boundaries of the fauces are the posterior border of the soft palate above, the palatine arches laterally, and the dorsum of the tongue. Below the fauces, the anterior wall of the pharynx is the posterior or pharyngeal dorsum of the tongue. On the posterior parts of the dorsum of the tongue lie irregular nodules of tissue known as the lingual tonsils. The lateral wall of the passageway of the fauces houses the large palatine tonsils. The lingual tonsils in the anterior aspect, the palatine tonsils in the lateral aspect, and the pharyngeal tonsils or adenoids in the posterior and superior aspects form a ring of lymphoid tissue known as the Waldeyer ring.

Hypopharynx

The laryngeal part of the pharynx, or hypopharynx, extends from just above the level of the hyoid bone superiorly to the lower border of the cricoid cartilage inferiorly, narrowing rapidly to become continuous with the esophagus. The anterior wall is formed laterally by mucosa on the medial surface of the thyroid cartilage and centrally or medially by the larynx and its appendages. Above are the epiglottis and the aditus of the larynx. Below the aditus, the anterior wall of the pharynx is also the posterior wall of the larynx. Lateral to the epiglottis are the lateral glossoepiglottic folds that form the anterolateral boundary between the oral and laryngeal parts of the pharynx. Below these folds, the hypopharynx extends forward around the sides of the larynx between this area and the thyroid cartilage. These bilateral expansions are the piriform recesses or sinuses.

The intrinsic portion of the larynx consists of the epiglottis, false vocal folds, laryngeal ventricles, paired true vocal folds, and arytenoid cartilages in the posterior aspect. Contained within the aryepiglottic folds are the paired corniculate and cuneiform cartilages. The space between the two vocal folds is the glottis.

The muscles of the pharynx are the superior, middle, and inferior constrictors. These muscles look like ice cream cones inserted into one another. They gradually merge to form the cricopharyngeus muscle at its inferior extent and then the esophagus. Each constrictor inserts with the corresponding muscle of the opposite side and the midline into a posterior midline raphe. These muscles are innervated by cranial nerve X through the pharyngeal plexus. Dehiscence in the pharyngeal constrictors may give rise to Zenker diverticula. Immediately lateral to the pharyngeal muscles are the great vessels of the neck and cranial nerve X.

Larynx

The major structural elements of the larynx are the shield-shaped thyroid cartilage and cricoid cartilages (Fig. 1.16). They join through the cricothyroid joint. The superior cornua of the thyroid ala articulate through several small cartilages with the hyoid bone. Overlying the structure of this skeletal framework are the infrahyoid muscles, which include the paired sternohyoid, sternothyroid, omohyoid, and thyrohyoid muscles.

The epiglottis is formed of fibroelastic cartilage and has multiple perforations that allow free access of lymphatic drainage or tumor to the preepiglottic space. The preepiglottic space is a C-shaped space bounded superiorly by the median glossoepiglottic ligament, inferiorly by the thyroid cartilage, anteriorly by the thyrohyoid membrane, and posterolaterally by the epiglottis and aryepiglottic folds. Free dissemination of tumor can occur within the preepiglottic space. The paired arytenoid cartilages provide an attachment for the vocal ligament and movement of the vocal folds. The intrinsic muscles of the larynx are innervated by the recurrent laryngeal nerve. The exception is the cricothyroid muscle, which is innervated by the superior laryngeal nerve. The recurrent laryngeal nerve enters inferiorly and laterally to the cricothyroid articulation through the Killian-Jamieson area. The recurrent laryngeal nerve on the left originates over the aortic arch and ascends in the neck to innervate the larynx. On the right, this structure goes around the subclavian artery.

THE NECK

Cervical Triangles

The prominent landmarks of the neck are the hyoid bone, the thyroid cartilage, the trachea, and the sternocleidomastoid muscles (Fig. 1.17). The sternocleidomastoid muscles divide each side of the neck into two major triangles, anterior and posterior. The anterior triangle of the neck may be further delimited by the strap muscles into the superior and inferior carotid triangles. The posterior triangles or lateral triangles of the neck are formed by the posterior border of the sternocleidomastoid muscle anteriorly, the clavicle inferiorly, and the anterior border of the trapezius muscle

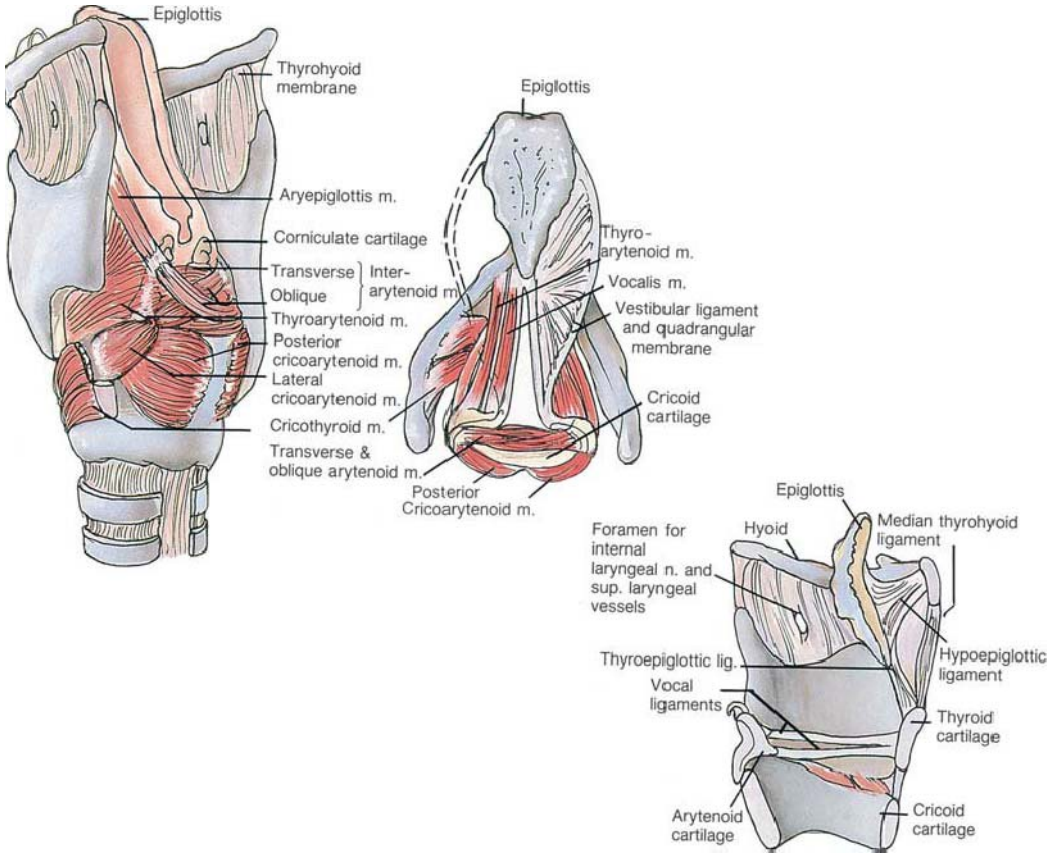

Figure 1.16 Larynx.

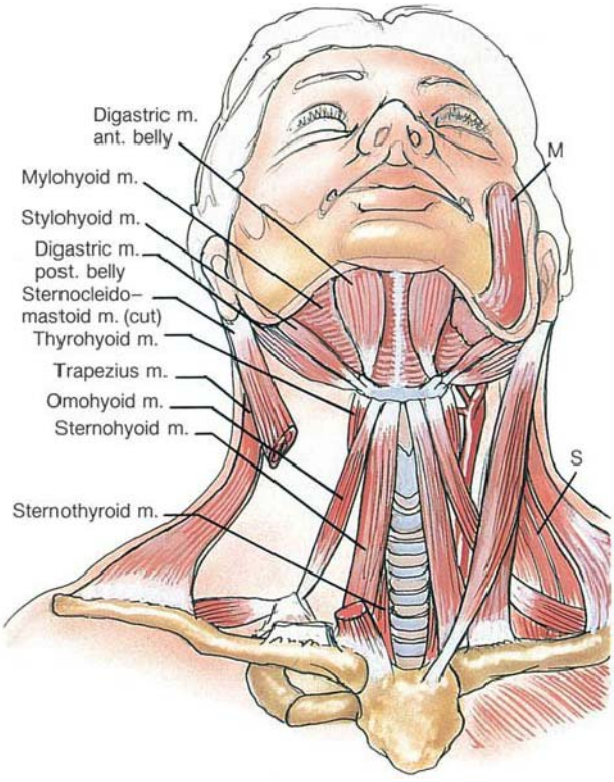

Figure 1.17 Muscles and triangles of the neck. *S*, scalene muscle; *M*, masseter.

posteriorly. The omohyoid muscle divides this triangle of the neck into a small inferior subclavian triangle and a larger posterior occipital triangle. Deep to these muscles are the scalenes, which form much of the muscle mass of the posterior and lateral portions of the neck. The brachial plexus and subclavian artery course between the anterior and middle scalene muscles. The subclavian vein courses anteriorly to the anterior scalene muscle.

Inferior Portion of the Neck

In the inferior root of the neck and closely associated with the brachial plexus are the paired phrenic nerves that course medially to innervate the diaphragm (Fig. 1.18). These nerves originate in the ventral rami of the cervical plexus of the third, fourth, and fifth cervical nerve rootlets. The subclavian artery gives rise to the thyrocervical trunk. The transverse cervical and suprascapular arteries usually course laterally over the surface of the phrenic nerve. This relation allows identification of these structures. The vagus nerve lies further medially and is contained within the carotid sheath. It shares the sheath with the common, internal, and external carotid arteries and jugular vein. Posterior to the carotid sheath lies the cervical sympathetic nerve. On the surface of the carotid sheath lie the ansa hypoglossi nerves.

Lateral Portion of the Neck

The dominant structure of the lateral cervical triangle is the spinal accessory nerve. It emanates from the posterior border of the sternocleidomastoid muscle in close association with the splay of nerves of the cervical sensory plexus. It innervates the trapezius muscle on its inferior aspect in close association with the transverse cervical artery or suprascapular artery, which variably supplies the trapezius muscle.

Arterial Supply

The two common carotid arteries differ in length because the right carotid usually arises from the brachycephalic artery behind the sternoclavicular joint and the left arises from the arch of the aorta (Fig. 1.19). Both arteries end by bifurcating into the internal and external carotid arteries. Over the lateral aspect of these arteries course the paired hypoglossal nerves. The internal carotid artery is situated more posteriorly and has no branches. The external carotid artery has branches and lies slightly anteriorly. This information can be crucial in differentiating the two vessels for ligation. From its origin, the internal carotid artery ascends directly toward the carotid canal and is crossed laterally, in ascending order, by the hypoglossal nerve, occipital artery, posterior belly of the digastric and associated stylohyoid muscle, and the posterior auricular artery. Still higher and close to the base of the skull, the external carotid artery is anterolateral to the internal carotid artery, and the stylopharyngeus muscle and associated glossopharyngeal nerve, the pharyngeal branch of the vagus, and the stylohyoid ligament all pass laterally to the internal carotid, between it and the external carotid artery.

After its origin in the carotid triangle, the external carotid artery passes upward, deep to the posterior belly of the digastric and stylohyoid muscles, and crosses the styloglossus and the stylopharyngeus muscles on their lateral aspects; then, parallel to the ramus of the mandible, it passes into the deeper portion of the parotid gland. The external carotid artery has branches to the superior thyroid, lingual, facial, ascending pharyngeal, occipital, posterior auricular, maxillary, transverse facial, and superficial temporal arteries.

Venous Supply

The veins of the neck vary considerably in their connections with each other and in their relative sizes (Fig. 1.20). Those conducting blood downward from the head and face include the external jugular, anterior jugular, internal jugular, and vertebral veins. At the base of the neck are the suprascapular and transverse cervical veins and the subclavian vein, which unites with the internal jugular vein to form the brachycephalic or innominate vein. The subcutaneous veins and the external and anterior jugular veins are especially variable in size and course.

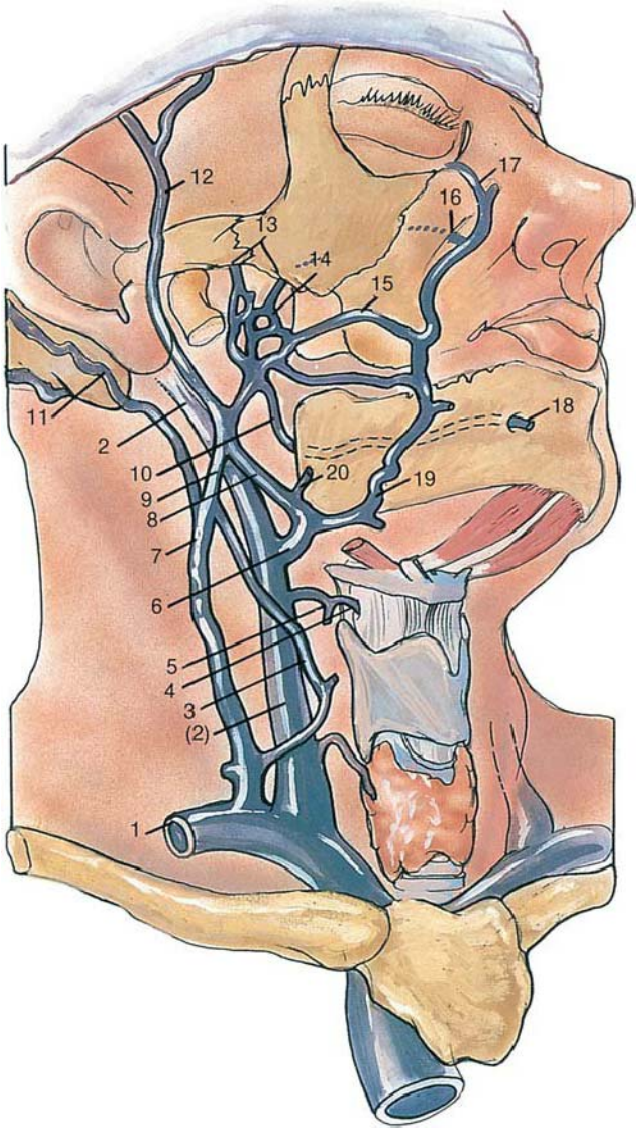

Figure 1.20 Venous supply of the neck. *1*, Subclavian vein; *2*, internal jugular vein; *3*, anterior external jugular vein; *4*, superior laryngeal vein; *5*, superior thyroid vein; *6*, common facial vein; *7*, posterior external jugular vein; *8*, retromandibular vein, anterior division; *9*, retromandibular vein, posterior division; *10*, inferior alveolar vein; *11*, posterior auricular vein; *12*, superficial temporal vein; *13*, deep temporal vein; *14*, pterygoid plexus; *15*, deep facial vein; *16*, infraorbital vein; *17*, angular vein; *18*, mental vein; *19*, facial vein; *20*, external palatine vein.

Lymphatic Vessels

The lymphatic system of the neck consists of numerous lymph nodes intimately connected with each other by lymphatic channels and the terminations of the thoracic and right lymphatic ducts. The deep cervical lymph nodes are numerous and prominent, and many of them are large. They form a chain embedded in the connective tissue of the carotid sheath. Most are in that portion of the sheath around the internal jugular vein. They extend from the base of the skull to the base of the neck. Two nodes that deserve particular attention are the superior jugulodigastric node at the junction of the internal jugular vein and the posterior belly of the digastric and the inferior juguloomohyoid node at the junction of that muscle and the internal jugular vein. Block resection of the neck in a standard radical or modified manner relies on reproducible and consistent lymphatic drainage pathways for success.

Viscera

The visceral structures of the neck include the thyroid and parathyroid glands, a portion of the pharynx, the larynx, the trachea, the esophagus, and sometimes portions of the thymus (Fig. 1.21). The thyroid gland lies below and on the side of the thyroid cartilage, covered anteriorly by the infrahyoid muscles. A pyramidal lobe of the thyroid may extend superiorly from the isthmus that connects the two lobes of the thyroid gland. On the posterior surface of the thyroid gland lie the paired parathyroid glands. Successful parathyroid exploration and thyroidectomy depend on accurate identification and preservation of the recurrent laryngeal nerves and identification of the parathyroid glands. Landmarks that are used successfully to locate these

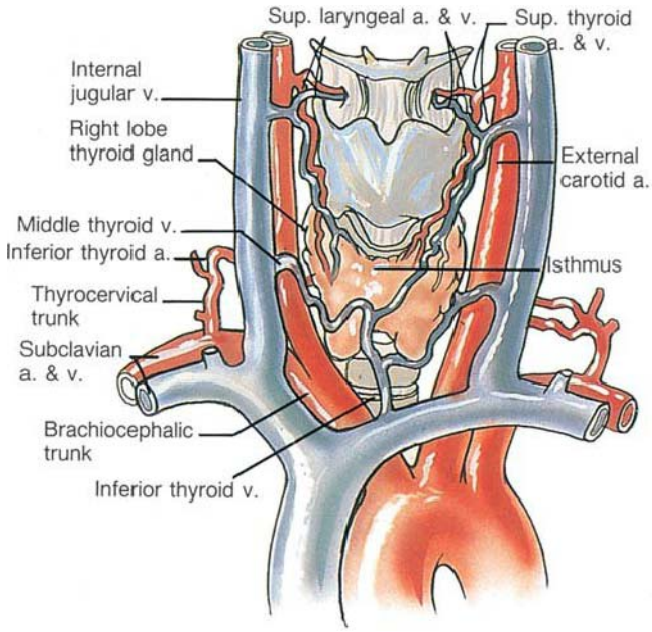

Figure 1.21 Thyroid and parathyroid glands.

structures include the trachea, common carotid artery, and inferior thyroid artery, which form a triangle within which the surgeon usually finds the recurrent laryngeal nerve. Lymphatic drainage occurs along the peritracheal nodes. Venous drainage similarly is directed inferiorly along the inferior thyroid veins.

The four or more parathyroid glands develop from the dorsal extremities of the third and fourth pharyngeal pouches. As the thyroid and thymus and their associated parathyroid glands move caudally from the region in which they originate, the thymus normally descends beyond the level at which the thyroid halts. The parathyroids from the fourth pouches (superior parathyroid glands) usually are situated more craniad than the thyroid gland, and those derived from the third pouches (inferior parathyroid glands) are usually freed from the thymus and become associated with the thyroid gland at its lower pole. Both sets of parathyroid glands usually are situated on the posterior aspect of the lateral lobes of the thyroid gland, but there are many exceptions. Because of the manner in which they arise and migrate into the neck, the glands often are displaced and may be situated in other portions of the thyroid gland or lie above or below it.

2 Basic Surgical Principles

A. Bradley Boland *Emily Rogers*

PREOPERATIVE ASSESSMENT AND EVALUATION

Frequently overlooked by surgeons, the preoperative assessment is one of the most important components to planning a successful operation. The preoperative evaluation begins in the office with a detailed history and physical. All medications, including herbal supplements and dosages, must be recorded. It is also prudent to discuss illicit drug use, alcohol consumption, and tobacco use with the patient as these social habits can affect anesthesia and postoperative outcomes. Functional capacity can be assessed with questions about activities of daily living. Patients who can climb one flight of stairs or walk several blocks expend four or more metabolic equivalents (METs) and typically require no further cardiac workup (Table 2.1) (1). However, patients who can do little more than dress themselves will need further cardiac assessment prior to surgery (2). Based on the information gathered at this initial visit, the patient's overall health status can be judged and further assessment completed as necessary.

The goal of preoperative assessment is to identify patients who are at risk of perioperative complications and work to limit their risk prior to surgery. The most important component is the cardiac assessment. The American College of Cardiology (ACC) and American Heart Association (AHA) created a task force in 1997 to develop perioperative guidelines to better direct the preoperative workup. These guidelines were updated in 2007 and provide tools to evaluate cardiac status prior to noncardiac surgery (1). The guidelines are summarized in algorithm format (Fig. 2.1) (1). The primary decisions are limited to two essential questions—should the patient undergo additional cardiac evaluation prior to surgery, and is a perioperative beta-blocker indicated to reduce the risk of cardiac complications?

While the algorithm appears complex at first glance, it is actually a very simple tool to quickly answer these questions. The first step is to identify the urgency of the procedure, as emergent or more urgent procedures cannot wait for thorough cardiac evaluation and possible revascularization. The next step is determining the risk of the procedure being performed. For most otolaryngology cases, the risk will be low to intermediate as the high-risk category is generally reserved for vascular operations. Once these steps are completed, the patient's current functional status and symptoms as well as past medical history are utilized to determine the need for further preoperative cardiac assessment, such as stress testing and potential referral for formal cardiology evaluation.

The algorithm utilizes five clinical risk factors—history of ischemic heart disease, prior or compensated heart failure, diabetes mellitus, chronic kidney disease, and cerebral vascular disease—to identify and stratify a patient's risk for cardiac complications. In addition, any symptoms of active myocardial ischemia, heart arrhythmia, valvular heart disease, or decompensated heart failure should prompt a formal cardiology referral. Per the ACC/AHA guidelines, an ECG should be obtained in all patients with a history of coronary artery disease, peripheral vascular disease, or congestive heart failure who are undergoing head and neck surgery. Currently, there is no consensus on minimum age at which an ECG should be routinely obtained. If an abnormality is identified on ECG, then this would also prompt referral to a cardiology subspecialist for further evaluation.

Perioperative beta-blockade has been shown to reduce the incidence of perioperative cardiac risk in patients with any of the five clinical risk factors listed in the prior paragraph. Beta-blockade should be considered in these higher risk patients even in emergent operations. Usually patients with chronic medical conditions that predispose them to heart disease will have a primary internal medicine

TABLE 2.1 ESTIMATED ENERGY REQUIREMENTS FOR VARIOUS ACTIVITIES

1 MET	Can you … Take care of yourself? Eat, dress, or use the toilet? Walk indoors around the house? Walk a block or 2 on level ground at 2–3 mph (3.2–4.8 kph)?	4 METs	Can you… Climb a flight of stairs or walk up a hill? Walk on level ground at 4 mph (6.4 kph)? Run a short distance? Do heavy work around the house like scrubbing floors or lifting or moving heavy furniture?
4 METs			Do light work around the house like dusting or washing dishes?
		>10 METs	Participate in moderate recreational activities like golf, bowling, dancing, doubles tennis, or throwing a baseball or football? Participate in strenuous sports like swimming, singles tennis, football, basketball, or skiing?

Modified from Hlatky, et al. A brief self administered questionnaire to determine functional capacity (the Duke Activity Status Index). *Am J Cardiol* 1989;64:651–654, copyright 1989, with permission from Elsevier, and adapted from Fleisher LA, et al. *Circulation* 2007;116(17):e418–e419, with permission. Ref. (28).
kph, kilometers per hour; MET, metabolic equivalent; mph, miles per hour.

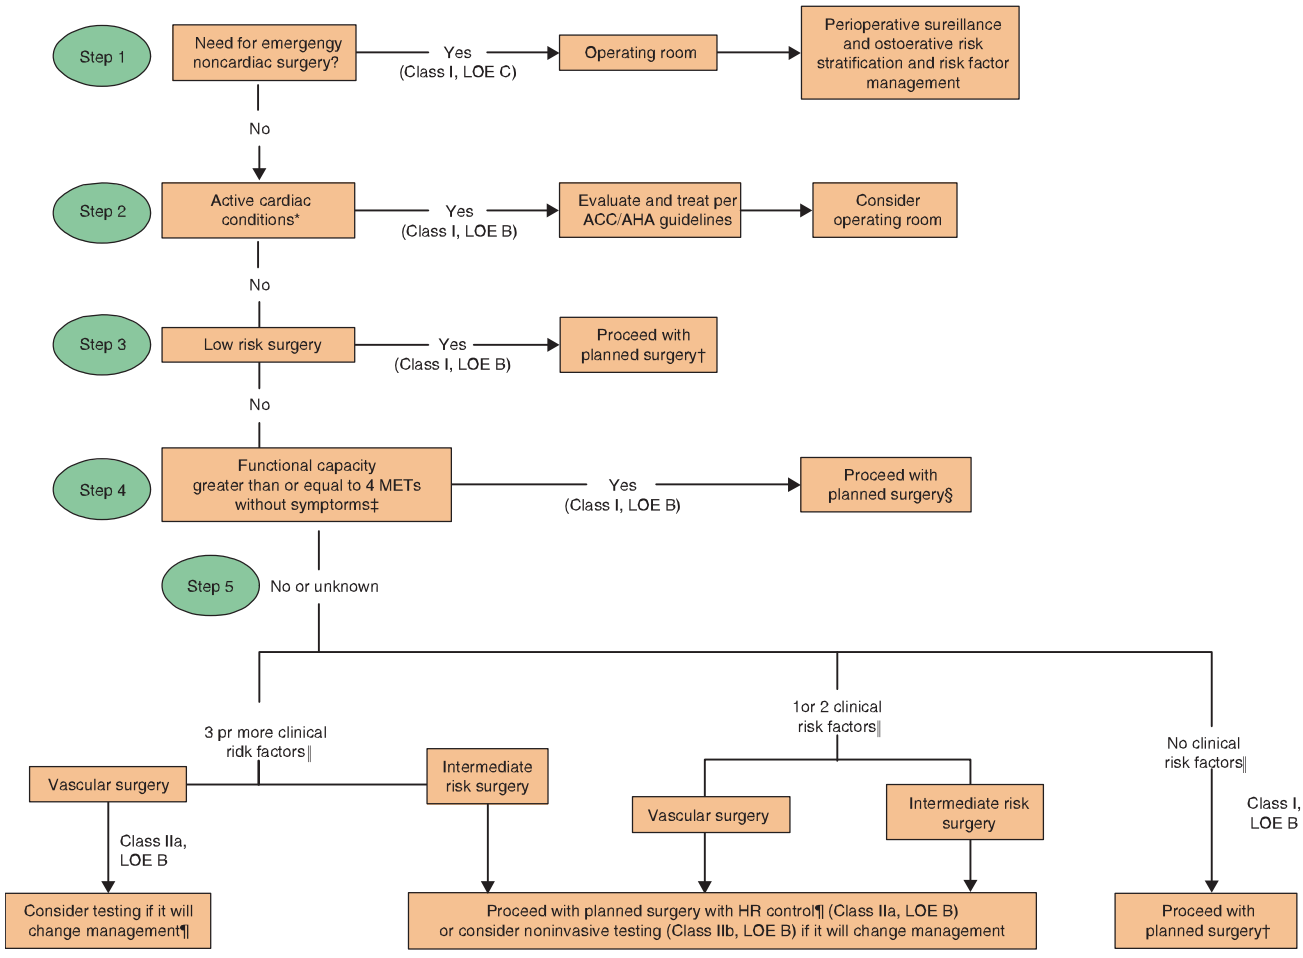

Figure 2.1 Cardiac evaluation and care algorithm for noncardiac surgery based on active clinical conditions, known cardiovascular disease, or cardiac risk factors for patients 50 years of age or greater. From Fleisher LA, et al. *Circulation* 2007;116(17):e418–e419, with permission.

physician who can assist in the decision-making process when the operation is done on an elective basis.

After the cardiac assessment, the next most important factor in preoperative management is pulmonary evaluation. Patients with a history of restrictive or obstructive pulmonary disease, long-term smokers, oxygen-dependent patients, and/or a recent history of upper respiratory infection need further pulmonary workup. Pulmonary studies including a chest x-ray, arterial blood gas, or pulmonary function testing are examples of routine tests required for preoperative risk assessment and management. Often patients with chronic lung disease will need detailed evaluation and recommendations for perioperative management from a pulmonary subspecialist (3).

Renal and hepatic function also affect perioperative patient management and risk. The clearance of medications from the body is nearly always affected by either renal or hepatic function. Therefore, both should be assessed with careful history and laboratory assessment as indicated to appropriately choose and dose perioperative medications including antibiotics, beta-blockers, sedatives, and analgesics. Patients with asymptomatic elevations in liver-associated enzymes often can proceed to surgery without delay. However, patients with active hepatitis or cirrhosis do have an increased risk of postoperative complications and mortality, which may require postponement of surgery and/or aggressive preoperative planning for risk reduction (4). Hepatic dysfunction alone can be an independent risk factor for perioperative morbidity and mortality, especially in patients undergoing high-risk operations. Bleeding complications are increased due to the propensity for coagulopathy from decreased liver synthetic function and thrombocytopenia from splenic sequestration associated with severe liver disease. Head and neck operations are considered low to intermediate risk, and the studies that have defined perioperative risk include few head and neck operations (5). One study limited to the evaluation of perioperative risk in otolaryngology cases found a history of hepatitis was associated with complications, but only five patients with hepatitis or a history of hepatitis were included in the analysis (6). Another recent study found no statistically significant increase in overall flap complications in patients with hepatic dysfunction although there was an increase in incidence of postoperative flap hematoma (7).

Perioperative medication management is essential even in the absence of renal or hepatic impairment. A complete medication review including over-the-counter and herbal supplements is important not only to assess a patient's known comorbidities but also to prevent intra- and postoperative complications. In general, most chronic medications can be taken with a glass of water the morning of the operation. Common exceptions to this rule include oral hypoglycemic medications, chronic anticoagulation, diuretics, and nonstatin hypolipidemics. However, the risk and benefit for continuing each individual medication should be addressed preoperatively. Type I and II diabetic patients on chronic insulin therapy will need to develop a perioperative plan with their primary physicians or endocrinologists especially for longer, more complex operations.

Anticoagulation and antiplatelet therapy alone can involve significant preoperative planning and execution. The indication for anticoagulation is important for devising a plan for perioperative management. For instance, if a patient is taking anticoagulation for the treatment of acute venous thromboembolic (VTE) disease or has a mechanical heart valve, it is much more important to maintain therapeutic anticoagulation throughout the perioperative period than if a patient is taking anticoagulation for prevention of VTE, in patients with a remote history of cerebrovascular accident, or in patients with atrial fibrillation. Antiplatelet therapy planning is likewise dependent on the reason for use. In most cases, antiplatelet therapy will be discontinued due to operative bleeding risk. Exceptions are when bleeding risk is minimal or discontinuation will cause a life-threatening complication, that is, coronary artery stent thrombosis.

INFORMED CONSENT

Consent is the process of obtaining permission to perform a surgical procedure after thoroughly informing the patient about all aspects of the procedure. Consent is typically obtained from the patient on whom the procedure will be performed; however, should the patient in need of surgery be unable to provide consent, the next of kin or legal guardian can provide consent. Examples of the types of patients who are unable to personally give consent are not limited to the following: patients under the age of 18, patients who are intubated and/or sedated, and patients with mental health problems or mental handicaps. Patients giving consent must have decision-making capabilities.

The consent must state in layman's terms the procedure that is to be performed as well as the risks, benefits, and alternatives. Risks of the surgical procedure, including possible complications, should be discussed with the patient. Benefits of the procedure should also be made clear to the patient. Alternatives to the procedure should be reviewed and it should be clarified that the alternative to refuse surgery is the patient's ultimate choice. In acquiring consent, the patient must understand his or her disease process, the goals of the procedure, and possible outcomes.

UNIVERSAL PRECAUTIONS

In 1987, the Centers for Disease Control (CDC) published a report on the prevention of blood-borne pathogen transmission in the world of health care. This document, in comparison to a similar report by the CDC in 1983, made recommendations for health care workers, which would eventually become known as "Universal Precautions." This

new report highlighted the importance of consistent use of body fluid precautions regardless of the patient's bloodborne infection status. It was wisely felt that the patients' accurate infection status was often unknown and therefore safest to implement universal precautions.

The CDC recommends the use of gloves, barrier gowns, and mucous membrane barriers, including eye protection and masks, when there is contact with body fluids or blood. Gloves are to be worn by the health care worker any time there is contact with blood or body fluids and must be changed after contact with each patient. Gowns should be donned any time a splash of blood or body fluids is expected, especially during procedures. Mucous membrane barriers, masks and eye protection, should also be worn if a splash is expected in order to prevent exposure to the eyes, nose, or mouth.

STERILE TECHNIQUE

The idea of sterile technique has evolved over the last 150 years. Joseph Lister is regarded as the father of aseptic surgical technique. In the late 1860s, Lister adopted carbolic acid for use in the operating theater in the attempt to decrease surgical wound infections and the development of gangrene. At the time, carbolic acid was being used to treat sewage odors with great success. Lister's surgical team washed their hands with carbolic acid, soaked bandages in carbolic acid, and cleaned the surgical site and instruments with carbolic acid. Lister found a dramatic decrease in surgical wound infections with the use of carbolic acid; however, carbolic acid was toxic to those who used it chronically (8). In time, the use of iodine- and alcohol-based skin preparations for both patients and surgeons evolved, and the use of surgical gloves became standard practice after being introduced by William Halsted. This section discusses aspects of sterile technique in the operating room in the hopes that surgical site infection rates can continue to improve.

Surgical Hand Scrub

The surgical hand scrub is the first step to aseptic technique and must be understood and mastered. The scrub includes the hands, forearms, and fingernails to remove debris and reduce the microbial load on the skin. Fingernails should be kept short and all jewelry removed.

The two most common types of antiseptic skin agents are povidone–iodine and chlorhexidine gluconate. Each agent has advantages and disadvantages and all surgeons should have a working knowledge of these different agents attributes. Both povidone–iodine and chlorhexidine gluconate are fast acting and effective against gram-positive organisms, gram-negative organisms, fungi, enveloped viruses, and *Mycobacterium tuberculosis*. The povidone–iodine scrub is inactivated when in contact with blood or sputum and has the potential for obvious cloth and skin staining. It should also be noted that chronic use of povidone–iodine while pregnant can lead to fetal hypothyroidism (9).

Chlorhexidine gluconate when combined with alcohol provides a quick scrub and is not affected by contact with blood or sputum. It is also effective for a longer period of time, which provides more coverage during a surgical procedure and even following the operation. Chlorhexidine should be avoided in the middle and inner ear as it can cause ototoxicity (10).

Surgical Site Preparation

After arrival to the surgery center or hospital, the patient's street clothes should be exchanged for a hospital gown. When considering hair removal, if possible it is best not to remove any hair as all forms of preoperative hair removal result in an increase in wound infection rates. Nonetheless, sometimes hair in the operative field must be removed and should be removed by clipping only. Shaving should always be avoided as it can cause skin nicks that can then harbor bacteria and cause wound infections.

The CDC and Surgical Care Improvement Project (SCIP) both advise clipping hair just prior to surgery if hair removal is required. Patients need to be instructed not to shave the operative site before surgery. In a prospective study completed by Cruse and Foord, surgical site infections were found to be highest in those shaved with a rate of 2.3%. Patients who underwent hair clipping had an infection rate of 1.7%, and those who had no form of hair removal had an infection rate of 0.9% (11).

The goal of surgical site preparation is to clean the skin and reduce the microbial load before incision. In the past, povidone–iodine or chlorhexidine–alcohol solutions were used interchangeably. Today, new studies show that chlorhexidine–alcohol is superior and should be used preferably. In a study comparing the two, 849 patients undergoing surgery were assigned either povidone–iodine or chlorhexidine–alcohol for preoperative skin antisepsis. The povidone–iodine group had a surgical site infection rate of 16% compared to 9.5% in the chlorhexidine–alcohol group (12).

INSTRUMENTS AND SUTURE MATERIAL

There are hundreds of different types of surgical instruments available to the surgeon, and with time most surgeons learn these different instruments; however, most surgeons operate with only a handful of trade standards. We review the most commonly used instruments within the operating room in this section.

Instruments

Scalpels

Scalpels are composed of two parts—the handle and the blade. Scalpel handles and blades are made of either carbon

steel or stainless steel—carbon steel blades are generally sharper and stainless steel blades last longer. Bard-Parker and Beaver are the two major types of scalpel handles. The Bard-Parker is the most widely used scalpel handle—it has a wide, flat handle and easily holds the Bard Parker no. 10, no. 11, and no. 15 blades. The Beaver handle is typically round and fits with a no. 67 or no. 64 blade and is useful for delicate, more defined procedures.

Scalpel blades come in all shapes and sizes, but the most commonly used blades are the no. 10, no. 11, and no. 15. The no. 10 blade is wide with a convex belly and is ideal for large incisions—it is not appropriate for small, meticulous incisions. The no. 11 blade tapers to a sharp point, making it very good for punctate, stab-like incisions or for incision/drainage incisions. The no. 15 blade is the most extensively used blade because it is small and great for precise incisions.

Scissors

Scissors are one of the main components in the surgeon's instrument armamentarium. There are several different types of surgical scissors and each has a specific purpose in the operating theater and should be used appropriately. The most commonly used scissors are the suture cutting scissors. These can be either curved or straight, but should only be used to cut suture. Using fine cutting scissors to cut sutures will lead quickly to very dull blades.

Scissors can be short or long, blunt or sharp tipped, or curved or straight. Metzenbaum scissors are specifically for sharp meticulous dissection and come in several different sizes. Mayo scissors are heavier for blunt dissection work. Iris scissors are typically short, sharp, and ideal for head and neck surgeries. Gradle scissors are similar to Iris scissors but tend to have a shaper tip for more delicate dissection.

Forceps

The most common forceps used within the operating suite are the Adson, Debakey, and Bishop-Harmon forceps. Forceps can be smooth, toothed, or serrated. It is important to not use serrated forceps on the skin as this can lead to a crush injury. Adson forceps are either smooth or toothed and are used for picking up skin edges. Debakey forceps are used within wounds for grasping delicate structures—they should never be used on skin. Bishop-Harmon forceps are small and lightweight and ideal for fine skin work.

Suture Material

Suture material is broken down into two major types—absorbable and nonabsorbable. Absorbable suture is enzymatically digested and loses tensile strength around 60 days. The most commonly used absorbable sutures are surgical gut, polyglactin (Vicryl), polydioxanone (PDS II), glycolic acid (Maxon), and poliglecaprone 25 (Monocryl). Nonabsorbable suture material is not hydrolyzed and maintains tensile strength. The most commonly used nonabsorbable sutures are silk, nylon, polypropylene (Prolene), and polyester (Dacron, Ethibond). It should be noted, however, that while silk is referred to as a "nonabsorbable" suture material, it is a naturally produced fiber and is absorbed by the body after a prolonged period of time.

Suture material is further divided into monofilament and braided classes. Monofilament suture is composed of one single strand of material and pulls through tissue easily with less trauma. Braided suture is made up of several strands of material and is easy to handle. One drawback of using braided suture is the possibility of organisms to reside between the strands and thus lead to a higher rate of wound infections (13).

Size of suture is important when closing different types of wounds. The size of suture is calculated by the diameter of the suture to handle a specific tensile strength. Suture size is described using zeros—the higher number of zeros equals a fine, small suture. For example, 2-0 Vicryl is much thicker and stronger than 4-0 Vicryl and the same is true for all types of suture material.

Other important factors to consider when choosing suture material are the memory, elasticity, and tissue reactivity of different types of material. Memory is the ability of a suture material to return to its original configuration. Sutures with increased memory are more difficult to handle and require more knots. Sutures with high memory are glycolic acid (Maxon), polypropylene (Prolene), and polydioxanone (PDS II). Elasticity of a suture material refers to the suture's ability to stretch and then return to its original length. Elasticity is important when dealing with wounds that are prone to postoperative swelling. Tissue reactivity is the amount of inflammation produced in response to the suture material. Studies show that synthetic and monofilament sutures have the least amount of tissue reactivity (14).

BODY POSITIONING AND EXPOSURE

One of the most important and often overlooked principles in surgery is achieving adequate exposure of the surgical site. Excellent exposure is obtained with careful preoperative planning and continuous attention to detail. In order to gain adequate exposure, the patient must be positioned appropriately. For example, when preparing for a thyroidectomy the neck must be extended to expose the operative field. This specific exposure can be aided with the placement of an axillary roll to further extend the neck. Attention to patient positioning preoperatively allows for an easier experience intraoperatively.

ANTIBIOTIC SELECTION

Preoperative antibiotics are administered to prevent surgical site infections. Wounds are classified into clean,

TABLE 2.2 WOUND CLASSIFICATION (15)

Class	Definition
Clean	No breaks in sterile technique, No inflammation, Noncontaminated skin
Clean–contaminated	Small break in sterile technique, Entry into GI, respiratory, or GU tracts with no gross spillage
Contaminated	Major break in sterile technique, Major contamination from GI, GU, or respiratory tracts
Dirty	Infected wound with purulent material

clean–contaminated, contaminated, and dirty depending on the anatomical site of the procedure (Table 2.2). Most clean cases do not require prophylaxis; however, this is controversial and is usually at the surgeon's discretion. All cases involving the gastrointestinal tract, including the oropharynx, should receive prophylactic antibiotic coverage.

Prophylactic antibiotics must be given within 1 hour of incision. Studies show that antibiotic concentration within tissues is optimal when given just prior to skin incision (16). The SCIP Guidelines, which were developed to reduce surgical site infection rates, also require that prophylactic antibiotics be given within 1 hour before incision. Should the operation exceed 6 hours or one to two half-lives of the antibiotic, then repeating the antibiotic intraoperatively should be considered. If prophylactic antibiotics are continued postoperatively, they should not be administered more than 24 hours after surgery end time. Studies indicate that the continuation of prophylactic antibiotics past 24 hours provides no benefit in preventing surgical site infections (17). Another potential drawback of prolonged antibiotic administration is the development of drug-resistant bacteria.

Preoperative antibiotic selection is determined by the anatomical location of the procedure and any patient allergies to specific antibiotics. The antibiotic selected should have bactericidal coverage for organisms that are most likely present in that particular anatomical location. If antibiotics are to be administered in a clean operation, then cefazolin and cefuroxime are the recommended antibiotics. Most wound infections following clean cases are secondary to *Staph* or *Strep* species and therefore, first- or second-generation cephalosporins provide adequate coverage. In patients who have a known drug allergy to cephalosporins, vancomycin or clindamycin can be used. For procedures involving the oral cavity, oropharynx, laryngopharynx or esophagus, antibiotics should cover aerobic and anaerobic bacteria and oral flora. Ampicillin/sulbactum, amoxicillin/clavulanate, or clindamycin provides adequate coverage. Major head and neck surgical cases that involve skin and oral or pharyngeal incisions are high risk for mixed infections. Coverage with clindamycin plus either gentamicin, tobramycin, ceftazidime or aztreonam provide coverage.

POSTOPERATIVE CARE

Postoperative care following head and neck surgery varies according to the complexity of the procedure; however, many will remained hospitalized for a minimum of 1 day. Postoperative complications, such as deep vein thrombosis and upper respiratory infections or pneumonia, should be avoided with methodical prophylaxis. Postoperative care is a responsibility of not only the physician, but also the nursing staff and patient. Expectations should be discussed with the patient, his/her family, and the nursing staff.

Dressings, wounds, and incision sites should be checked postoperatively for the development of a hematoma, evidence of bleeding, or early wound infection. Rapid development of a hematoma postoperatively, especially in the neck, can require a return to the operating room for evacuation. Early signs of wound infection such as erythema or drainage from the wound may necessitate removal of sutures and packing of the wound.

Postoperative glucose control is imperative. Diabetics need close glucose monitoring both pre- and postoperatively. In a study by Latham in 2001, it was shown that in patients undergoing coronary artery bypass grafting who had glucose values greater than 200 postoperatively had a twofold increase in surgical site infections (18). More recently, studies have emerged from the cardiothoracic literature that argue moderate glucose control [129–179] rather than tight glucose control [<126] results in better patient outcomes. Bhamidipati et al. (19), reporting from the University of Virginia in 2011 in a cohort of 4,658 cardiac bypass patients, found that patients with moderate glucose control had a lower mortality (2.0%) and complication rate (11.1%) than those patients with tight glucose control (2.9%, 19.4%, respectively). Consequently, diabetics must be followed closely and judicious use of sliding scale insulin should be implemented as needed.

VENOUS THROMBOEMBOLISM PROPHYLAXIS

Complications related to VTE are common in patients undergoing surgical procedures. The incidence of symptomatic deep venous thrombosis (DVT) and pulmonary embolism (PE) varies among surgical specialties (20,21).

In general, surgical specialties with high risk for such complications include orthopedics, neurosurgery, general surgery (especially major abdominal surgery); while specialties with low risk for such complications include urology, gynecology, and otolaryngology (22).

Venous prophylactic measures have been shown to reduce the incidence of perioperative VTE complications. These include mechanical measures (e.g., pneumatic

compression devices) and pharmacological measures (e.g., unfractionated heparin/low molecular weight heparin). As a result, attempts have been made to tailor prophylactic therapy to patients based on differential risk profiles (Table 2.3) (22).

One such approach, by the American College of Chest Physicians (20), relies on grouping patients by surgical specialty, then risk stratifying individual patients within each group. In risk stratifying individual patients, the age of the patient, the presence/absence of malignancy, the type of procedure (major/minor surgery), and a previous history of VTE are all factors that are considered.

While specific guidelines regarding prophylaxis have been formalized for patients undergoing orthopedic surgery, general surgery, and neurosurgery, this is not the case with otolaryngologic procedures. A first step in this process is to attempt to quantify the incidence of VTE complications in patients undergoing otolaryngologic procedures. Several retrospective reviews have addressed this question.

Moreano et al. (23) from the University of Iowa reporting in 1998 found the incidence of DVT and PE in their cohort of 12,805 patients to be 0.3% and 0.2%, respectively. This being more common in patients undergoing head and neck surgery (0.6%, 0.4%) and less common in patients with head and neck trauma (0.1%, 0.1%) and general otolaryngology (0.01%, 0.04%). They found patient age and the presence or absence of pneumatic compression to be independent risk factors.

Lee et al. (24) from the University of Toronto reporting in 2008 on their cohort of approximately 9,835 patients reported an overall incidence of DVT and PE to be 0.1% and 0.05%, respectively. They also noted highest incidence in patients undergoing major head and neck surgery. Chen et al. (25) from Memoral Sloan Kettering Cancer Center in their cohort of 6,759 procedures reported results similar to those noted by Lee et al. (24).

Innis and Anderson (21) from the Lahey Clinic in Boston reported that in their cohort of 6,122 patients that the overall incidence of DVT and PE was 0.1% and 0.02%, respectively. The incidence of DVT in patients treated for malignancy was 0.6% and without malignancy 0.01%. Innis and Anderson compared their results with those obtained by Moreano, and speculated that the reduced incidence of VTE in their group might be due to the use of pneumatic compression and subcutaneous heparin in all admitted patients. They further concluded that patients undergoing otolaryngologic procedures are a low risk for VTE complications. This conclusion is supported by a recent report regarding the incidence of VTE after thyroid and parathyroid surgery of 0.16% without prophylaxis, but with a serious bleeding complication rate of 1.58% in those given pharmacoprophylaxis (26).

Innis and Anderson recommend the following: (a) Early mobilization with or without the use of pneumatic compression in low-risk patients. (b) Pneumatic compression or pharmacologic prophylaxis for moderate-risk patients. (c) Both pneumatic compression and pharmacologic prophylaxis for high-risk patients. A similar algorithm was developed by Davidson et al. (27) for patients undergoing plastic surgical procedures.

It should be stressed, however, that decisions regarding prophylactic measures to prevent VTE should be based

TABLE 2.3 LEVELS OF THROMBOEMBOLISM RISK AND RECOMMENDED THROMBOPROPHYLAXIS IN HOSPITAL PATIENTS FROM THE AMERICAN COLLEGE OF CHEST PHYSICIANS (2008) (20)

Levels of Risk	Approximate DVT Risk without Thromboprophylaxis, %[a]	Suggested Thromboprophylaxis Options[b]
Low risk		
Minor surgery in mobile patients	<10	No specific thromboprophylaxis
Medical patients who are fully mobile		Early and "aggressive" ambulation
Moderate risk		
Most general, open gynecologic or urologic surgery patients	10–40	LMWH (at recommended doses), LDUH bid or tid, fondaparinux
Medical patients, bed rest or sick		
Moderate VTE risk plus high bleeding risk		
High risk		
Hip or knee arthroplasty, HFS	40–80	LMWH (at recommended doses), fondaparinux, oral vitamin K antagonist (INR 2–3)
Major trauma, SCI		
High VTE risk plus high bleeding risk		Mechanical thromboprophylaxis[c]

Note: The descriptive terms are purposely left undefined to allow individual clinician interpretation.
[a]Rates based on objective diagnostic screening for asymptomatic DVT in patients not receiving thromboprophylaxis.
[b]See relevant section in this chapter for specific recommendations.
[c]Mechanical thromboprophylaxis includes IPC or VFP and/or GCS; consider switch to anticoagulant thromboprophylaxis when high bleeding risk decreases.

on an individual patient basis after full evaluation of the surgical procedure, its likely impact on the patient, and patient risk factors.

HIGHLIGHTS

- Five clinical risk factors are used to stratify a patient's risk for cardiac complications prior to surgery. They are history of ischemic heart disease, prior or compensated heart failure, diabetes mellitus, chronic kidney disease, and cerebral vascular disease.
- Fetal hypothyroidism can occur with chronic povidone–iodine use while pregnant. Chlorhexidine in the inner ear can cause ototoxicity.
- Hair removal should be avoided if possible. If hair removal is required, hair should be removed by clipping just before surgery rather than shaving.
- Prophylactic antibiotics continued after surgery should not be administered for more than 24 hours after surgery.
- The decision to start VTE prophylactic measures should be based on an individual patient basis.

3 Perioperative Management Issues

David M. Barrs

This chapter presents selected aspects of medical management in the perioperative period, which is defined as the time just before, during, and after the operative procedure.

PREOPERATIVE EVALUATION

History and physical examination remain the cornerstones of the preoperative evaluation, with particular attention to specific conditions such as diabetes, bleeding disorders, and insufficiency of cardiac, pulmonary, and renal systems. In an era of cost containment, laboratory tests, radiographic examination, and specialty consultation are performed on an outpatient basis and are tailored to finding information that could modify or delay surgery (1–7). The incidence of abnormal laboratory results is extremely low in the asymptomatic patient and, in general, routine laboratory tests are not ordered in patients younger than 50 years. Healthy pediatric patients undergoing minor procedures such as pressure-equalizing tube placement should need no laboratory or radiographic evaluation. Pregnancy testing should be obtained for any woman of childbearing age because it may be in the best interest of the mother and fetus to consider a delay of elective surgery. Patients with specific medical conditions need more extensive examinations tailored to their problems. Current American College of Surgeons and American Society of Anesthesiology recommendations for preoperative testing are mentioned in the appropriate sections (4–7).

PREOPERATIVE MALNUTRITION

Protein–calorie malnutrition is associated with immunosuppression, poor wound healing, decreased basal metabolic rate, longer and more expensive hospital stays, and a higher mortality rate. Most otolaryngology patients are well nourished, but this is not the case with many head and neck cancer patients who have difficulty maintaining adequate oral intake to prevent weight loss. In the surgical patient, mild to moderate malnutrition is defined as an unintentional weight loss of 6% to 12% of the usual body weight in the preceding 3 to 6 months or 80% to 85% of ideal body weight. Severe malnutrition is suggested with weight loss greater than 12%, serum albumin less than 2.5 g/dL, serum prealbumin less than 5 mg/dL, serum transferrin less than 200 mg/dL, and decreased immune function manifested as total lymphocyte count less than 900 mm^3 (8–12).

Patients with mild to moderate malnutrition may undergo most otolaryngology surgeries, with attention given to nutrition in the postoperative period; however, severe malnutrition should be treated with 7 to 10 days of nutritional replacement before elective surgery. The daily caloric requirement for most hospitalized adults is 25 to 35 kcal/kg of body weight. Protein is usually required at 0.5 to 1.0 g/kg/day, but the critically ill patient may need an increase to 1.5 to 2.0 g/kg/day. Daily caloric requirements (basal energy expenditure) can be estimated by formulas such as the Harris-Benedict scale, available in standard nutrition textbooks, although the values may have to be increased 1.25 to 1.5 times due to the stress of surgery. Because poor oral intake is presumed to have caused the malnutrition, most replacement therapy should be in the form of total parenteral nutritional (TPN) therapy or enteral feedings. Enteral feedings are preferable to TPN for several reasons, including providing more nutrients, less likelihood of hyperglycemia, promotion of immune function, elimination of a central catheter, buffering of gastric acid, and less expense (10,11). Enteral feedings can be either a blenderized normal diet or a nutritionally complete commercial formula with an energy supply of 1 to 2 kcal/mL or higher. For nasogastric tubes, gravity bolus feedings are usually given at an initial rate of 50 to 100 mL every 4 hours, increasing to 240 to 360 mL every 4 hours. Continuous feedings may be preferable to bolus

since they constantly buffer gastric acid, reduce aspiration risk, and have smaller residual volumes. They can be started at 25 to 30 mL/h and increased after 24 hours by 25 mL/h until the target intake is reached. The limiting factors in the volume of tube feedings include vomiting, cramping, abdominal distention, and diarrhea. Because regurgitation or aspiration is a risk of tube feedings, residual gastric volume should be checked every 4 hours and before each tube feeding. A gastric residual volume of 300 to 400 mL may signal intolerance for gastric tube feedings. In patients with long-term nutritional needs, a percutaneous endoscopic gastrostomy or surgically placed jejunostomy tube often is required. Jejunal tubes require continuous peristaltic pump infusion at a slower rate and with isotonic solutions. In severely malnourished patients, caution must be used because of the "refeeding syndrome," caused by a reactive hyperinsulinemia secondary to the sudden intake of glucose. Particular attention is paid to fluid overload and congestive heart failure, cardiac dysrhythmias, glucose intolerance, and electrolyte abnormalities such as hypophosphatemia, hypokalemia, and hypomagnesemia.

For patients who are unable to take nutrition by the gastrointestinal tract, replacement should be with TPN delivered through a central venous line. Consultation with the appropriate dietary service is essential. A common TPN solution has at least 1 kcal/mL and contains 500 mL each of 50% dextrose and 500 mL of 10% amino acids, with added vitamins, electrolytes, and trace elements. Fat emulsion composed of soybean or safflower oil as a 10% to 20% solution, 250 to 500 mL, can be given as little as weekly to supply essential fatty acids. The three components with additives can also be mixed in a 3-L bag, termed "3-in-1 solution," and given over a 24-hour period and is often used to simplify administration. In general, the infusion is started with 1,000 mL in the first 24 hours and increased as tolerated to 2,000 mL/day. Two liters of solution provides at least 2,000 to 2,500 cal/day and essential nutrients. It is important in both enteral nutrition and TPN to provide enough water to prevent azotemia and hypernatremia. Some formulas now contain substances previously thought to be "nonessential" such as arginine, glutamine, and omega-3 fatty acids. These "immunonutrition" solutions have been found to decrease the incidence of infections.

The safety of TPN requires frequent monitoring. Vital signs and glucose should be monitored every 6 hours initially. When the patient is on a stable regimen, glucose, weight, caloric and protein intake, serum electrolytes, and blood urea nitrogen (BUN) can be checked twice weekly. Liver-function studies, serum magnesium, total protein, albumin, transferrin, triglycerides, complete blood count (CBC), prothrombin time (PT), and iron levels are measured weekly. Meticulous care of the central catheter is required to prevent catheter-site infection.

Tube feedings are withheld on the day of surgery. TPN is tapered before surgery and should not be given intraoperatively because of the risk of hyperglycemia. In the postoperative period, feeding as early as possible, either by mouth or tube feeding, is encouraged, and postoperative TPN should be used only if enteral feedings cannot be accomplished within 5 to 7 days after surgery. For tube feedings, water may be provided within hours of the termination of surgery, whereas full-strength formula at a rate of 30 mL/h can be started on the first postoperative day for most patients.

HEMATOLOGIC ABNORMALITIES

Blood Components and Transfusion

Specific indications for preoperative transfusion are discussed in the following sections (13–16). Rapid correction of hematologic deficiencies usually depends on blood transfusions. Whole blood is rarely used; it is separated into its components for safety and efficiency (Table 3.1). The broadest coverage for urgent surgery in patients with coagulation abnormalities is fresh frozen plasma (FFP), which contains all the clotting factors, although no platelets are present, and the fibrinogen level is low. Fibrinogen transfusion is no longer used because of the high risk of viral transmission; cryoprecipitate is used to treat low fibrinogen levels.

Serious complications to transfusions include immune-mediated hemolytic reactions, anaphylactic reactions, and transmission of viral or bacterial disease. More recently, the immunosuppressive effect of the antigenic components of blood, termed immunomodulation, has been recognized (15). Far more common are mild hypersensitivity and nonhemolytic febrile reactions. Pretreatment with an antihistamine (diphenhydramine, 50 mg) and acetaminophen usually minimizes such reactions and permits completion of the transfusion. Of specific concern is the patient who has undergone massive transfusion. Volume overload may be minimized by using packed red blood cells. Hyperkalemia, hypokalemia, hyperammonemia, and

TABLE 3.1 BLOOD COMPONENTS

Fraction	Indication
Packed red blood cells	Acute hemorrhage, symptomatic anemia
FFP	Replace multiple coagulation deficits, specific coagulation deficits if factor concentrates unavailable
Platelets	Quantitative and qualitative platelet disorders
Cryoprecipitate	Low fibrinogen, factor VIII, von Willebrand's factor XIII
Factor concentrates	Specific factor deficits, especially VIII, IX, V
Plasma derivatives	Immunoglobulin, high titer antibodies

acidosis require specific treatment. Massive transfusions may lead to significant thrombocytopenia and coagulation factor depletion. Clotting studies such as activated partial thromboplastin time (aPTT), PT or international normalized ratio (INR), which is PT corrected to an international standard, platelet counts, and fibrinogen levels should be monitored for any sign of coagulopathy. Hypothermia can be minimized by warming blood and crystalline replacement. Citrate toxicity can cause a decrease in ionized calcium. Replacement with calcium gluconate (10 mL, 10%, IV) is reserved for symptomatic hypocalcemia and is not given prophylactically.

Alternatives to transfusion should be considered preoperatively. For elective surgery, the patient can be an autologous donor with a maximum of 1 U donated every 72 hours, up to 72 hours before surgery, as long as the patient maintains a hematocrit of greater than 33%. Autologous donation, however, is not cost-effective unless significant blood loss is anticipated. Other methods include isovolemic hemodilution (removal of whole blood preoperatively, replacement with crystalloid, and reinfusion after acute blood loss), intraoperative autotransfusion (return of processed blood from the operative field), or use of erythropoietin for several weeks preoperatively to stimulate red blood cell production.

Erythrocyte Abnormalities

A preoperative hemoglobin level should be obtained on all female patients but is not necessary in asymptomatic male patients younger than 50 years who do not have a history of bleeding or anemia. Anemia is significant because of the decreased oxygen-carrying capacity available during anesthesia (13–17). The previous minimal acceptable hemoglobin level of 10 g/dL for surgery or transfusion has been lowered to 6 to 7 g/dL, which is adequate for tissue oxygen delivery if circulating volume is normal. Healthy patients or chronically anemic patients may undergo surgery safely at these levels if minimal blood loss is expected. Two situations may require transfusion: active bleeding and coronary artery disease. In the patient with coronary artery disease, the hemoglobin should be increased to 10 g/dL or hematocrit of 30% (15) before surgery.

Elevated hemoglobin and hematocrit levels, respectively, greater than 16.5 g/dL and 55% in males and 15.3 g/dL and 52% in females also requires evaluation to exclude polycythemia or erythrocytosis (17,18). The most common cause is a relative polycythemia caused by reduced plasma volume from conditions such as dehydration. Tests, such as an increased chromium 51 red cell mass and low erythropoietin levels, may point toward a diagnosis of Polycythemia vera, which is associated with a higher incidence of thrombotic and hemorrhagic perioperative complications. For elective surgery, the patient should ideally be stable for several months before surgery. A hematocrit of 45% can be obtained with phlebotomy by removing 125 to 200 mL of blood every other day in healthy individuals, and slower removal in older patients or patients with cardiac disease. Platelet counts should ideally also be reduced to less than 500,000. In the emergency situation, whole blood can be removed and replaced with crystalloid.

Two hemoglobinopathies are of concern. The first is sickle cell disease. Sickle cell trait is not associated with increased surgical risk. In patients with the homozygous condition, the level of hemoglobin S should be reduced to avoid sickling crisis or acute chest syndrome during anesthesia or during the postoperative period. The simplest method is to transfuse to a hemoglobin level of 10 g/dL before surgery. Hypoxia, hypernatremia, hypothermia, acidosis, and volume depletion should be avoided. Hypotonic fluids should be given to decrease blood viscosity (17,18). The second hemoglobinopathy is glucose-6-phosphate dehydrogenase deficiency, which causes oxidant damage to hemoglobin within erythrocytes and is almost exclusively seen in men. Preoperative screening for this deficiency should be performed if a family history of the deficiency or unexplained hemolysis exists. The condition is not a risk for surgery, but certain medications should be avoided in the postoperative period to minimize the risk of hemolysis.

Platelet Abnormalities

Thrombocytopenia is defined as a platelet count of less than 140,000/mL (13). For otolaryngologic surgery with minimal anticipated blood loss, a platelet count of 20,000/mL may be sufficient, but the platelet count should be 50,000/mL for more major surgery. Each unit of platelets for transfusion will increase the platelet count 5,000 to 10,000/mL, and the platelet half-life is usually 2 to 3 days, unless increased destruction occurs. Ideally, the platelet count should be maintained above 20,000/mL for 3 to 4 days postoperatively. Thrombocytopenia developing in the postoperative period is unusual unless massive transfusion has been necessary, but sepsis, disseminated intravascular coagulation (DIC), and drug-induced thrombocytopenia must be considered.

Qualitative platelet disorders with abnormalities in platelet function may exist even with a normal platelet count. Platelet dysfunction may be present if a patient has a history of uremia or dialysis, liver disease, von Willebrand disease (vWD), abnormal bleeding from previous surgery, or with a recent history of ingestion of aspirin, nonsteroidal anti-inflammatory drugs (NSAIDs), or other medicine, such as penicillin, that may affect platelet function. Aspirin is the most potent of the cyclooxygenase (COX) inhibitors, and irreversibly inhibits platelets for 5 to 7 days. Other NSAIDs, such as ibuprofen, are competitive inhibitors, and the platelet dysfunction can be reversed with desmopressin acetate (DDAVP). The selective COX-2 inhibitors, such as celecoxib, in usual doses do not cause platelet dysfunction. Thienopyridine class agents, such as clopidogrel, and glycoprotein 2b/3a receptor inhibitors, such as abciximab,

prevent platelet aggregation, and are not reversible. Tests for qualitative platelet dysfunction can be considered. In the past, a bleeding time was performed, but this test is now considered a global screening test, is often inadequate to identify many causes of platelet dysfunction, and is not useful as a predictor of bleeding during surgery. Current evaluation includes tests for platelet aggregometry, membrane glycoproteins, capillary tube shear testing, and should include screening for deficiency in von Willebrand factor (vWF), necessary for platelet adhesiveness. DDAVP may reverse the action of some platelet inhibitors such as NSAIDs or elevated BUN, may increase vWF, and may partially reverse the platelet dysfunction. Platelet transfusions or administration of DDAVP should be performed if emergency surgery is necessary. In elective surgery, medications causing platelet dysfunction should be stopped between 4 and 10 days before surgery, except in certain conditions such as the recent insertion of drug eluting cardiac stents.

Disorders of Hemostasis

The yield of routine preoperative coagulation studies, such as PT, aPTT, and platelet counts, is quite low unless the patient's history indicates a bleeding problem. This history should be searched carefully for congenital or acquired abnormalities of bleeding (18,19) (Table 3.2).

The perioperative management of patients receiving anticoagulant therapy requires specific comment. Heparin augments the effects of antithrombin (previously termed antithrombin III), which inhibits clotting enzymes, specifically factor Xa and thrombin (20). Low-molecular-weight heparins (LMWHs), such as enoxaparin, are increasingly used for deep venous thrombosis (DVT) prevention andginactivate factor Xa more than thrombin. LMWH has several advantages over heparin, including less risk of heparin-induced thrombocytopenia, longer subcutaneous injection half-life, and less necessity for monitoring anticoagulant effect. Warfarin, the most common anticoagulant, is given orally and is a vitamin K antagonist that decreases production of vitamin K–dependent clotting factors. Direct thrombin inhibitors, such as bivalirudin, are irreversible, but may cause less bleeding than heparin, so are preferred during procedures such as percutaneous coronary angioplasty. The need for anticoagulation should be discussed with the patient's primary care physician, and the method of preoperative discontinuation of the anticoagulant should be based on the estimated risk of DVT, pulmonary embolism (PE), or stroke (19). Patients in a low-risk category may simply have warfarin discontinued 2 to 3 days before surgery and restart it after surgery. Low-risk patients include those with aortic valve prosthesis or a resolved cause of a previous DVT. High-risk patients, such as those with a history of emboli of cardiac origin, atrial fibrillation, or mitral valve disease or prosthesis, should have warfarin discontinued several days before surgery and replaced with heparin. Intravenous heparin should be used to increase the aPTT to 1.5 to 2 times normal levels. Twelve hours before surgery, heparin should be discontinued, and the PTT will return to normal by the time of surgery. The effect of warfarin may be counteracted with vitamin K administration, as indicated in Table 3.2.

If surgery is imminent in a patient after anticoagulation with a warfarin product, 2 to 4 U of FFP may be given to correct the coagulation-factor deficiencies immediately while vitamin K takes effect. Repeated PT or INR tests should be

TABLE 3.2 DISORDERS OF HEMOSTASIS

Disorder	Corrective Action
Inherited deficiency	
Hemophilia A (VIII)	Factor VIII concentrate or recombinate VIII, FFP, CP Minor defect: DDAVP
vWD (VIII, vWF)	DDAVP (except type 2B vWD) Intermediate purity factor VIII with high vWF CP
Hemophilia B (IX)	Factor IX or recombinate IX concentrate (preferred) FFP (note: CP does not contain IX)
Acquired deficiency	
Liver disease	Rapid reversal: vitamin K, 10 mg, SC or IV, q12h × 3 days
Vitamin K deficiency Warfarin administration	FFP 2–4 U Monitor dose with PT or INR
Heparin	Protamine, 1 mg neutralizes 100 U heparin (avoid overcorrection—monitor aPTT)
DIC	FFP, CP, platelets

FFP, fresh frozen plasma; CP, cryoprecipitate; aPTT, activated partial thromboplastin time; PT, prothrombin time; INR, international normalized ratio; DIC, disseminated intravascular coagulation; vWD, von Willebrand's Disease.

performed to evaluate the results of therapy. If an emergency situation arises in the heparinized patient, either with unfractionated heparin or LMWH, protamine sulfate may be given to antagonize heparin immediately. Unlike heparin, however, LMWH is only partially reversed with the administration of protamine making it less safe in patients at high risk of bleeding (15,20,21). Caution, however, should be used in the administration of protamine because it can induce a hypercoagulable state. On the one hand, it is crucial to note that FFP will not correct the coagulation defect caused by heparin. On the other hand, reversal of direct thrombin inhibitors must be accomplished by infusion of FFP.

The timing for restarting anticoagulants postoperatively depends on patient risk factors for thrombosis and embolization and on the type of surgery and hemostasis obtained at surgery. In neurotologic surgery and possibly airway surgery in which bleeding would present a life-threatening problem, anticoagulation should be delayed at least 36 to 48 hours. Rapid anticoagulation then is accomplished with intravenous heparin, whereas slower anticoagulation is accomplished simultaneously by restarting oral warfarin.

Intraoperative and Postoperative Bleeding

When the cause of intraoperative or postoperative bleeding is not an unsecured vessel, a search must be made for a coagulation disorder (15–18). Screening tests include CBC (hemoglobin, hematocrit, platelet count, and morphology), PT (INR), aPTT, qualitative platelet tests as noted earlier, and fibrinogen. Further testing and treatment depend on the findings of these preliminary tests as follows (15):

1. Normal PT and aPTT: The most common abnormality is impaired platelet activity, either thrombocytopenia or platelet dysfunction. Treatment is with platelet transfusion or DDAVP, as previously discussed. Other causes include factor XIII or fibrinogen deficiency.
2. Normal PT, abnormal aPTT: Drug-induced effect (heparin), vWD, or clotting factor deficiency, such as hemophilia, should be suspected and treated as noted earlier.
3. Abnormal PT and normal aPTT: Present with liver disease or warfarin anticoagulation, treated with vitamin K and FFP administration.
4. Both PT and aPTT abnormal: The first step is to repeat aPTT and PT testing to exclude laboratory error. If this is not present, then severe reductions in multiple clotting factors are present, and severe malnutrition with depleted vitamin K–dependent clotting factors, DIC, severe hemodilution, or nephrotic syndrome may be present.

Hemodilution and nephrotic syndrome coagulopathy is caused by decreased concentration of clotting factors, whereas DIC is the result of consumption of clotting factors. Moderate DIC initiates intravascular microthrombi, which lodge in critical organs and can produce adult respiratory distress syndrome or renal and hepatic failure. Severe DIC occurs when the intravascular microthrombi trigger an overwhelming fibrinolytic response and resultant dissolution of previously formed clots, leading to bleeding. The bleeding in DIC is the result of a cycle of clot formation and fibrinolysis, leading to consumption of clotting factors. In addition to the routine coagulation tests, a search is made for the presence of fibrin split products and D-dimer, the latter produced when plasmin acts on crosslinked fibrin. A high D-dimer level, especially greater than 2,000 ng/mL, is presumptive evidence of DIC (21). Treatment of DIC in the past had included the use of heparin to stop the clotting and allow return of clotting factors to more normal levels. Current recommendations for treatment are to remove the clotting stimulus (e.g., dead tissue, abscess), correct hypothermia, and correct blood loss with packed red cells and clotting factors with FFP and platelets.

THROMBOEMBOLIC DISEASES

DVT and PE are significant postoperative problems (17,22,23). Major risk factors are immobilization, history of thromboembolic disease, varicose veins, oral contraceptives and estrogen compounds, age older than 40 years, malignancy, central venous catheters, antiphospholipid syndrome, and hypercoagulable states such as erythrocytosis, thrombocytosis, and inherited thrombophilic disorders such as Leiden factor V mutation, prothrombin 20210 mutation, and deficiencies of substances antithrombin III, protein C, and protein S, which results in decreased lysis of clots.

Preventive Measures

Mechanical preventive measures usually are used first in otolaryngology patients. Any method designed to increase lower-extremity blood return is helpful. Traditional measures include early mobilization, leg elevation, elastic stockings, and physical therapy. A newer innovation is the external pneumatic compression boot, which is applied to the calf and thigh. The boot is intermittently inflated, the pressure held, and then deflated to massage blood up from the lower extremity. They should be considered for any patient who may not be mobilized early or who is undergoing a neurotologic, neurosurgical, or airway procedure in which prophylactic anticoagulation may not be indicated. Caution is used in patients with severe peripheral arterial vascular disease because vascular supply to the lower extremity may be compromised.

The pharmacologic methods of prevention of thromboembolic complications, such as heparin or warfarin, are quite effective, but they require starting the patient on treatment before surgery, which increases the risk of bleeding during surgery. The traditional use of heparin, 5,000 U, twice daily, in the perioperative period has been replaced by different protocols: (a) an adjusted dose of unfractionated heparin IV or SC to increase the aPTT by 2 to 3 seconds; or (b) LMWH, such as enoxaparin, 1 mg/kg,

q12h; (c) a factor Xa inhibitor, such as fondaparinux, 2.5 to 5 mg daily for adults greater than 50 kg., or (d) warfarin to increase the INR to 2–3.

Diagnosis

The risk of embolization from calf vein thrombosis is usually small, but thrombosis propagation to the more proximal femoral and iliac veins markedly increases the chance of pulmonary embolization. Accurate diagnosis of postoperative DVT is difficult but important to prevent unnecessary anticoagulant therapy. A positive Homan sign, unexplained fever, pitting edema, and localized discomfort or discoloration over leg veins may indicate underlying DVT. These signs, however, are quite insensitive and may give little indication of a serious DVT. D-Dimer testing, normally useful in DVT diagnosis, is always positive in the postoperative or trauma patient (21,22). If a duplex ultrasonography shows a noncompressible clot, a DVT can be assumed. Ascending contrast venography, with contrast material injected into a foot vein, has been largely abandoned due to the technical difficulty. If these tests are positive, then anticoagulation is instituted with unfractionated or LMWH, followed by warfarin. A search for underlying factors, such as hypercoagulable state, may be undertaken.

Pulmonary Embolism

Despite preventive measures, DVT and subsequent PE may develop (22,23). The diagnosis is difficult, but PE should be suspected in patients with sudden onset of tachypnea, dyspnea, chest pain, hemoptysis, hypoxia, delirium, or dysrhythmias. For patients at risk for PE where no contraindication exists, anticoagulation should be started while testing is performed. If significant clinical suspicion exists, further studies can include contrast-enhanced spiral computed tomography (CT) scan combined with a CT venogram of the pelvis and leg, a ventilation–perfusion (VQ) scan, magnetic resonance angiography, or pulmonary angiography. If the pulmonary CT scan shows one or more luminal filling defects, especially bilateral, the diagnosis of PE is almost certain (21). Conversely, if the VQ scan is normal, there is little chance of a PE. Pulmonary angiography is performed in high-risk patients with equivocal test results.

Management

If no contraindication exists, anticoagulation is necessary in all patients with proximal DVT and PE (23). In neurotologic, skull base, or procedures in the airway, the risk of bleeding must be considered. In other cases, heparin should be given immediately and continued for a minimum of 5 days, with the aPTT maintained in a range of 1.5 to 2 times control, while oral warfarin anticoagulant therapy is initiated to therapeutic levels. If the PE is massive, streptokinase, urokinase, or recombinant tissue plasminogen activator should be considered as thrombolytic therapy. Inferior vena caval interruption is used when anticoagulation is contraindicated or recurrent emboli are found in adequately anticoagulated patients.

ENDOCRINE ABNORMALITIES

Diabetes Mellitus

Hyperglycemia is defined as a fasting blood glucose (BG) level greater than 126 mg/dL, a pre-meal BG greater than 140 mg/dL, a random BG greater than 180 mg/dL, or a 2-hour glucose tolerance test glucose greater than 200 mg/dL (24–25). Multiple studies, both medical and surgical, have shown substantial increases in complications and mortality of hyperglycemic hospitalized patients (24–29). Approximately half of intensive care unit (ICU) patients and one-third of all hospitalized patients will be hyperglycemic during their hospitalization. Tight diabetic control is a challenge even for patients undergoing minor otolaryngology procedures and is critical in major procedures with prolonged hospital recoveries. Surgery and anesthesia increase production of stress hormones and worsen hyperglycemia.

Bedside capillary point of care (POC) testing is now the preferred method of BG monitoring as opposed to laboratory BG testing. Use of sliding scale insulin administration, which is a set amount of insulin for a given BG, is no longer recommended. A measurement of HbA1c aids in assessing average blood levels of glucose over the preceding 1 to 2 months. Oral hypoglycemic and non-insulin injectable antidiabetic medications are discontinued on admission. Insulin is the preferred method to achieve glycemic control in hospitalized patients. Recent recommendations use the concept of basal intermediate or long acting insulin once or twice daily with bolus rapid-acting or regular insulin before meals and at bedtime based on POC glucose testing (See Table 3.3). Patients who are not eating or on enteric nutrition have bolus insulin based on POC glucose testing every four to six hours. Supplemental "corrective" short or rapid acting insulin is given for BG levels above the pre-meal target of 140 mg/dL or random BG of 180 mg/dL (24). In the perioperative period, all insulin-dependent diabetics receive basal/bolus treatment, while Type 2 non-insulin dependent diabetics can have insulin treatment initiated based on BG measurements. Type 1 diabetics require insulin, even if fasting, to prevent severe hyperglycemia and ketoacidosis. Insulin is given subcutaneously (sc) as opposed to an IV bolus in hospitalized patients. Similarly, in surgery, the trend is away from IV bolus to either sc or continuous insulin infusion pumps. Tighter control of glucose levels requires close observation to prevent hypoglycemia, defined as BG less than 70 mg/dL. It is important that diabetics receive 3 g/kg of body weight each day of

TABLE 3.3 MANAGEMENT OF SURGICAL PATIENTS WITH HYPERGLYCEMIA

Basal–Bolus Insulin Treatment

Total daily insulin dose: 0.5 units insulin/kg × weight in kg
  0.2–0.4 units/kg in renal insufficiency, elderly, and lean patients
Example: Weight = 72 kg
  72 kg × 0.5 = 36 units insulin
  Basal dose (long acting, e.g., glargine insulin) = 18 units
    Example: Given once daily in AM or split twice daily
  Bolus dose (short or rapid-acting insulin) = 18 units in 3 divided doses
    Example: 6 units given before each meal
  Corrective dose = Short or rapid-acting insulin given in addition to the bolus dose for BG above optimal levels
    Example: Initial 2–6 units while basal and bolus doses adjusted

carbohydrates to prevent protein catabolism and lipolysis. Dextrose 5% in water at 100 mL/h provides 5 g glucose per hour.

Long-term management of poorly controlled patients is complex and best managed by the endocrinologist and multispecialty diabetic team. The otolaryngologist should know, however, basic management of postoperative increases in glucose. The most severe postoperative exacerbation is diabetic ketoacidosis (DKA) and is a true medical emergency with marked dehydration secondary to osmotic diuresis, hyperventilation in reaction to metabolic acidosis, and decreased levels of consciousness. The patient should be managed in the ICU. Immediate laboratory tests should include glucose (fingerstick or blood); potassium; serum ketones; other electrolytes such as magnesium, calcium, and phosphate; and blood gases to document the level of acidosis. All are repeated every 1 to 2 hours until the patient is stable, glucose is less than 250 mg/dL, and ketones have resolved. Cardiac monitoring is accomplished to exclude ectopy. Normal saline is given empirically over 20 to 30 minutes for volume repletion while test results are pending. The treatment of DKA is to give rapid-acting IV insulin, 10 to 15 U or 0.1 to 0.15 U/kg followed by the same dose hourly or via infusion pump. It is crucial, however, that potassium levels be determined and potassium replacement started at 10 to 40 mEq/h concurrently or before insulin to avoid profound hypokalemia, which can result from insulin facilitation of intracellular movement of potassium. The goal is to reduce the glucose level 50 to 75 mg/dL/h until the glucose level is 250 mg/dL.

In the less emergent situation, regular insulin is given at a dose of 4 to 10 U subcutaneously every 4 to 6 hours. Alternatively, a constant regular insulin infusion can be administered with a loading dose of 0.1 to 0.2 U/kg, followed by an infusion rate of 0.1 U/kg/h in a 0.9% sodium chloride solution. Blood glucose levels are measured every 1 to 2 hours. The patient then may be monitored during surgery in the same way as the well-controlled diabetic. Hyperosmolar nonketotic syndrome, characterized by hyperglycemia and dehydration, primarily requires restoration of intravascular volume and lower doses of insulin (0.05 to 0.15 U/kg/h). Discharge insulin or oral hypoglycemic agent dose depends on glucose control at the end of the patient's hospitalization.

Thyroid and Parathyroid Disorders

Patients with mild to moderate hypothyroidism may undergo emergency surgery with little increase in morbidity. For elective surgery, gradual replacement of hormone is preferred because rapid repletion can lead to relative adrenal insufficiency and angina in patients with coronary insufficiency. Synthetic levothyroxine, with a usual daily dose of 0.1 to 0.2 mg (1.8 mcg/kg/day), is the preferred replacement medication and may be given orally or intravenously in the same dose (30). The patient with severe hypothyroidism may have low temperature, hypotension, hyponatremia, hypoventilation, and hypoglycemia. Severe hypothyroidism can have an initial presentation postoperatively, especially in the elderly. Whether present in the preoperative patient needing urgent surgery or developing in the postoperative period, severe hypothyroidism can be treated with IV thyroxin, 200 to 500 mcg. Hydrocortisone, 100 mg IV every 12 hours, also should be given because adrenocorticotropin pituitary responsiveness to stress may be decreased (31). Hydrocortisone is continued until serum cortisol can be evaluated and pituitary responsiveness checked. Although fluid volume must be restored, free water clearance is diminished. Care must be taken with hypotonic intravenous solutions to avoid hyponatremia and water intoxication.

Elective surgery in hyperthyroid patients should be delayed, if possible, until the patient is in a euthyroid state. If urgent surgery must be performed in the thyrotoxic patient, iodines, propranolol, and thionamide antithyroid drugs, such as propylthiouracil (PTU) or methimazole,

should be used to reduce the risk of thyrotoxic crisis (30–33). PTU blocks thyroid hormone production, inhibits the conversion of thyroxine (T4) to triiodothyronine (T3), and usually is given in an oral dose of 100 to 200 mg three times daily. Methimazole is given either as divided doses of 10 mg every 8 to 12 hours, or as a single 20- to 40-mg daily dose. In the routine treatment of thyrotoxicosis, methimazole is preferred to PTU because fewer adverse reactions occur, especially PTU-induced hepatitis, and compliance is potentially higher with a single daily dose. PTU is preferred in pregnancy and the treatment of thyroid storm, the latter due to PTU blockage of extrathyroidal deiodination of T4 to T3. Iodides induce a transitory inhibition of thyroid hormone production and release from the gland and decrease vascularity of the gland, which lasts 10 to 14 days. Iodides can be given as a saturated solution of potassium iodide at a dose of 5 drops orally every 6 hours or Lugol's solution, 10 drops, three times daily. Palpitations, tachycardia, and tremor can be controlled with a beta-blocker such as propranolol in an initial dose of 20 to 40 mg, taken orally four times daily or 1 to 2 mg, given intravenously every 4 to 6 hours. Hydrocortisone should be given to counter relative adrenal insufficiency. Replacement thyroxine should be given postoperatively, and a thyroid-stimulating hormone and T_4 checked 6 to 12 weeks after surgery.

Thyrotoxic crisis, or thyroid storm, manifests by severe exaggeration of the classic symptoms of thyrotoxicosis and may develop intraoperatively or in the immediate postoperative period (30–33). The patient may have a marked fever, sweating, tachycardia, vomiting, abdominal pain, and delirium. Large doses of the same medications are given (Table 3.4). In the treatment of thyrotoxic crisis, the order of medical therapy is important. Although iodide blocks release of thyroid hormone, it also is the precursor for oxidation to iodine. For this reason, PTU is given first to prevent this oxidation used in hormone production, and then, at least 30 minutes later, iodide is given to block hormone release. Supportive therapy includes temperature control with acetaminophen or a cooling blanket. Sedation and oxygen therapy may be needed, and the patient should receive adequate glucose-containing intravenous solutions because of the high metabolic rate. Aspirin is contraindicated since it binds to thyroid binding globulin and displaces T4, increasing the available hormone.

TABLE 3.4 MEDICAL CONTROL OF THYROTOXIC CRISIS

1. Propylthiouracil, 200 mg, q4h or methimazole, 30 mg, q6h
2. Sodium iodide, 500 mg, IV, twice daily
3. Propranolol, 1–2 mg/min (total 10 mg) or 40–80 mg, PO, q6h, prn pulse >100
4. Dexamethasone, 4 mg, q6h, or hydrocortisone, 100 mg, IV, q6h
5. Replacement of volume deficit
6. Treatment of infections

Hypocalcemia, defined as a serum level less than 9 mg/dL if albumin is normal, may develop in any person undergoing parathyroid or bilateral thyroid surgery (32). After surgery, serum calcium and phosphate levels should be determined every 6 to 8 hours for the first several days, followed by daily levels thereafter. Serum ionized calcium alone is the optimal single measure if albumin levels are uncertain (31). If the calcium level decreases to less than 7.0 mg/dL, signs or symptoms of latent tetany should be sought. A positive Chvostek or Trousseau sign, hyperreflexia, numbness or tingling in the extremities, or circumoral paresthesias are indications to begin calcium replacement. Oral replacement can be accomplished with calcium carbonate, 250 to 500 mg, orally, four times daily, and vitamin D_3, 0.25 to 2.00 mg, orally, daily.

Laryngeal stridor, overt tetany, or seizures are medical emergencies and require IV calcium replacement. Calcium gluconate (10%) is less irritating than calcium chloride and is given as one to two ampules (10 to 20 mL) diluted in 50 to 100 mL of dextrose solution infused over a 10-minute period. Each ampule contains 1 g of calcium gluconate and 93 mg of elemental calcium. This emergency infusion of calcium gluconate can be repeated every 15 to 20 minutes, followed by a continuous infusion. The infusion can be prepared with six ampules of 10% calcium gluconate (540 mg elemental calcium) in 500 mL of D5W given at 1 mL/kg/h, giving approximately 1 mg/kg/h of elemental calcium (34). Deficiencies in magnesium, sodium, and albumin must be corrected. Overly rapid replacement of calcium can potentiate digitalis toxicity in cardiac patients. Hyperventilation in an anxious patient will cause a respiratory alkalosis with resultant worsening of the hypocalcemia. Patients with prolonged hypocalcemia may require oral calcium carbonate or calcium citrate replacement with 1.5 to 3 g each day of elemental calcium and vitamin D.

Adrenal Glucocorticoids

Adrenal insufficiency in otolaryngology patients is usually due to prior long-term steroid use with suppression of the hypothalamic–pituitary–adrenal axis (34–36). The normal oral daily maintenance dose of hydrocortisone is 20 mg in the morning and 10 mg in the afternoon. Prednisone is 4, methylprednisolone is 5, and dexamethasone is 25 times more powerful than hydrocortisone. Patients who have been taking as low a dose as prednisone 5 mg for 2 weeks in the preceding year are assumed to have suppressed endogenous production of cortisol and should be treated with supplemental steroids for surgery (34,37). Patients who are currently taking steroids, those with known adrenal insufficiencies, and even patients with Cushing syndrome also should be covered with supplemental steroids in the perioperative period. Large quantities of cortisol, in the range of 300 mg daily, are released from the adrenal gland during stresses such as surgery. The dose of administered steroids is designed to be in this same range (Table 3.5). Failure to

TABLE 3.5 REPLACEMENT IV HYDROCORTISONE FOR ADRENAL SUPPRESSION

Minor surgical procedures:
Usual daily corticosteroid dose
Additional 100 mg before surgery

Major surgical procedures:
100 mg the night before surgery
100 mg before surgery and every 8 h during surgery
100 mg, every 8 h, postoperatively for 24 h
50 mg, every 8 h, of the second postoperative day
Taper to maintenance over 3–5 d
Maintain 200–400 mg daily if ongoing stress or complication

provide replacement glucocorticoids can result in loss of vascular tone, with hypotension that is refractory to fluids or pressor agents. Other research, however, suggests that ongoing daily prednisone doses less than 10 mg or treatment with any dose completed more than 3 months previously does not suppress endogenous cortisone secretion and does not require supplemental therapy (25). If this approach is taken, the clinician should be ready to supply replacement corticosteroids if symptoms suggestive of adrenal insufficiency appear.

Primary adrenal insufficiency is rare but may first appear perioperatively as acute adrenal crisis. The symptoms are not specific and can include hypotension, weakness, dizziness, fever, nausea, vomiting, and abdominal pain. In the face of unexplained hypotension, adrenal insufficiency must be considered and treated empirically if hypotension is refractory. Blood should be drawn for measurement of serum levels of cortisol, adrenocorticotropic hormone (ACTH), electrolytes, glucose, BUN, and creatinine. After blood work is drawn, an immediate bolus of dexamethasone, 4 to 8 mg, or 100 to 200 mg of hydrocortisone is given intravenously, followed by fluids containing glucose and saline to correct volume deficiencies. Maintenance hydrocortisone is started, 100 mg IV, every 6 hours, until the condition stabilizes. The cortisol and ACTH levels should be sufficient to differentiate between pituitary or adrenal causes, but if not, a rapid 250-mcg ACTH stimulation test is performed to check peak cortisol response (should exceed 20 mcg/dL) (35). Mineralocorticoid replacement should not be necessary while the patient is receiving IV fluids. Both hydrocortisone and prednisone have mineralocorticoid effects, but dexamethasone does not.

Pituitary

The otolaryngologist often is involved in the removal of pituitary adenomas and other skull-base surgery. If a complete hormonal evaluation has not been performed, the surgeon should be aware of possible adrenal and thyroid insufficiency. More common, however, are perioperative diabetes insipidus (DI) and the syndrome of inappropriate antidiuretic hormone (SIADH) secretion (38,39).

Central DI is caused by a decreased level of antidiuretic hormone (ADH), which impairs kidney free-water reabsorption, leading to increased thirst and large volumes of dilute urine in the face of inappropriate hypernatremia and hyperosmolarity of the serum. In effect, the patient has a free-water deficit. Other conditions may mimic central DI, including nephrogenic resistance to ADH. The stress of surgery normally increases ADH secretion and free-water retention, resulting later in a water diuresis that may be mistaken for DI. Excessive intravenous fluid replacement also may result in a large urinary volume secondary to the input. Mannitol given during neurologic and skull-base surgery may produce an osmotic diuresis. A diagnosis of DI should be restricted to patients with urinary outputs greater than 200 mL/h with associated hypernatremia, increased serum osmolarity, and low urinary osmolality usually less than 300 mOsm. The diagnosis rests on measuring the urine osmolality response to administered ADH in the dehydrated patient. In DI patients, the urine osmolality increases at least 50% and often 200% to 400%. The patient should be monitored with frequent intake and output, body weights, urine osmolality, and serum sodium.

In mild cases, simple oral intake of water to satisfy thirst may provide adequate free water. In more severe cases or in the patient not taking water orally, IV 5% dextrose in water with only enough sodium to cover obligate sodium requirements is given. The volume should equal the urinary loss plus insensible losses. For high urinary volumes (i.e., 3 to 4 L daily), pharmacologic replacement should be considered as follows.

Treatment may be initiated with DDAVP, a long-acting vasopressin analogue given intranasally at a dose of 10 to 40 mcg daily or orally 0.1 to 1.2 mg daily, both in two to three divided doses. The parenteral preparation is 10 times the strength, given SC or IV, 2 to 4 mcg daily in two divided doses. An alternative is aqueous pitressin, which has the drawbacks of short duration of action and a vasoconstrictor effect, which may precipitate angina. The dose is 5 to 10 U two to four times daily. Only half the calculated free-water deficit should be supplied in the first 24 hours. In the postoperative patient, the condition will usually resolve over a 3- to 5-day period with conservative treatment of water replacement and judicious use of ADH compounds.

The SIADH secretion is characterized by "inappropriate" conservation of water, and manifest as euvolemic, hypoosmotic hyponatremia with a urine osmolality that is abnormally concentrated (greater than 100 mOSM) compared with serum osmolality (38,39). Because surgery and trauma cause ADH release, excessive administration of hypotonic IV solutions should be avoided. Treatment usually is accomplished by fluid restriction to 1,000 mL/day and use of 3% hypertonic saline if serum sodium is less than 110 mEq/L or seizures are present. Demeclocycline, which inhibits the renal effects of ADH, is used for prolonged treatment. A parenteral preparation, conivaptan,

blocks the effect of vasopressin on the V2 receptors in the kidney and produces an increase in water excretion (39). The dose is 20 mg given over 30 minutes, and then followed by 20 mg continuously over 24 hours for 1 to 3 days. Rapid correction should be avoided, especially in neurosurgical cases, to lessen the chance of cerebral overhydration and edema and permanent demyelinating neurologic damage from central myelinolysis. Correction of the hyponatremia should not exceed 10 to 12 mEq/L for 24 hours.

CARDIOVASCULAR DISORDERS

Current American College of Cardiology and American Heart Association guidelines for perioperative cardiovascular evaluation list four conditions that require evaluation before noncardiac surgery: (a) unstable coronary syndromes such as unstable or severe angina and recent myocardial infarction less than 1-month old; (b) decompensated heart failure; (c) significant arrhythmias such as high grade or Mobitz II atrioventricular block or supraventricular arrhythmias with uncontrolled ventricular rate, and (d) significant valvular disease such as aortic stenosis (40). Other risk factors for postoperative cardiovascular morbidity include (a) age older than 70 years; (b) peripheral vascular disease; (c) insulin-dependent diabetes; (d) creatinine greater than 2.0; (e) history of cerebrovascular disease (transient ischemic attack or stroke); and (f) poor functional capacity, less than 4 METS on the Duke Activity Status Index, which is the equivalent of climbing one flight of stairs (29). Head-and-neck surgery is classified as an "intermediate risk" surgery. In asymptomatic patients, a routine electrocardiogram (ECG) is recommended for patients older than 50 years and compared with any available prior ECGs. Noninvasive cardiac testing for patients with risk factors includes exercise stress test, myocardial perfusion imaging with tracers such as Thalium-201 in conjunction with exercise or pharmacologic stress, and dobutamine stress echocardiography. Invasive testing, such as coronary angiography, is reserved for patients at high risk or with positive noninvasive tests. If the patient is taking cardiac medications (e.g., digitalis), serum levels should be obtained to ensure optimal levels before surgery. Electrolytes like potassium, magnesium, and calcium should be measured to attempt to decrease the likelihood of perioperative dysrhythmias. Further preoperative considerations include cardiac consultation to set pacemakers to the uninhibited mode and to turn off internal defibrillators.

Recommendations for the use of beta-blocking medication in noncardiac surgery continues to evolve. The 2007 ACC/AHA guidelines recommended starting beta-blockers for higher risk surgery, but the subsequent Perioperative Ischemic Evaluation (Poise) study found a higher mortality and stroke risk (40,41). Initiating beta-blockers in high-risk patients (three or more risk factors or positive stress evaluations), and continuing beta-blockers in patients already taking them, are current recommendations (29). Ideally, beta-blockage therapy should be started several weeks before elective surgery and should be at a dose to lower the resting heart rate to 50 to 60 beats per minute. The therapy is relatively contraindicated for patients with asthma or bronchospasm, or who have a baseline heart rate less than 55, systolic blood pressure less than 100, or have a type II second-degree or third-degree heart block. Starting a patient with cardiac abnormalities on beta-blockade may be daunting for the otolaryngologist. Consultation with the primary care physician, the preoperative clinic, or use of standardized hospital protocol may be of help. Preoperative oral medication options can include metoprolol, 25 to 50 mg, twice daily; bisoprolol, 5 to 10 mg, daily; or atenolol, 50 to 100 mg, daily. Metoprolol and atenolol can be given IV in patients who cannot take oral medications.

Hypertension

Antihypertensive medications should be continued to the morning of surgery and resumed immediately postoperatively (42–44). As mentioned above, beta-blocking agents should be continued until surgery and resumed immediately postoperatively because sudden cessation can produce a withdrawal syndrome with sinus tachycardia, hypertension, myocardial ischemia, or tachydysrhythmias. The symptoms may mimic a variety of cardiac abnormalities, but they respond rapidly to resumption of IV beta-blockers, such as labetalol or metoprolol, or enalapril, an angiotensin-converting enzyme (ACE) inhibitor. Clonidine-withdrawal syndrome can be characterized by a hypertensive crisis that may need IV nitroprusside or phentolamine for control (42–44). Beta-adrenergic antagonists, such as propranolol, atenolol, and metoprolol, should not be used in clonidine withdrawal because the resulting unopposed alpha-adrenergic activity may precipitate a hypertensive crisis. Monoamine oxidase inhibitors and guanethidine should be discontinued 2 weeks before surgery because of the possibility of severe drug interactions or interference with circulatory reflexes.

Virtually all anesthetic agents are vasodilators and negative ionotropes, which may create the necessity for fluid infusion in excess of fluid losses during surgery. Pharmacologic agents may be needed to control blood pressure during surgery (43). On emergence from anesthesia, sympathetic tone in the vessels is restored, and blood pressure can increase significantly. Postoperative hypertension is defined as systolic blood pressure greater than 200 mm Hg, an increase in systolic blood pressure greater than 50 mm Hg, or a diastolic blood pressure greater than 100 mm Hg. Prolonged or extreme postoperative hypertension may lead to myocardial failure or increased risk of intracranial bleeding in neurotologic or skull-base procedures. In urgent situations, the pharmacologic agent of choice has been nitroprusside, but nicardipine, an easily titratable calcium channel blocker, is an attractive alternative because it does not carry a cyanide risk (Table 3.6). Esmolol, a beta-blocker and fenoldopam, a dopamine receptor agonist, can be used effectively in the postoperative period (43).

TABLE 3.6 PERIOPERATIVE PHARMACOLOGIC CONTROL OF HYPERTENSION

Agent	Action	Dosage	Comment
Nitroprusside	Arterial and venous dilator	0.25–10 mcg/kg/min	Agent of choice for severe hypertension. Cyanide danger over 4 mcg/min
Labetolol	Combination alpha-, beta-blocker	20–80 mg q 5–10 min to max 300 mg in 24 h or 0.5–2 mg/min IV infusion	Avoid in negative inotropic states (e.g., heart failure, heart block) or asthma
Nitroglycerin	Antianginal agent (coronary vasodilator)	Initial 5 mcg/min IV infusion pump increased by 5 mcg/min every 3–5 min to max 100 mcg/min	Used when nitroprusside contraindicated for severe coronary insufficiency, advanced renal or hepatic disease
Esmolol	Beta-blocker	500 mcg/kg/min for first minute then 50–200 mcg/kg/min	Does not increase cerebral blood flow and intracranial pressure
Fenoldopam	Dopamine agonist	0.03–1.6 mcg/kg/min	Preferred in renal disease

In postoperative hypertension, it is extremely important to search for a cause rather than simply treat the hypertension with pharmacologic agents. The most common cause of postoperative hypertension is pain, but the differential diagnosis should include hypervolemia, ventilatory or respiratory failure, residual effects of anesthesia or intraoperative pressor agents, anesthetic-induced hypothermia and shivering, distended stomach or bladder, or manifestations of preexisting hypertension. Treatable causes of postoperative hypertension should be corrected before pharmacologic agents are given because severe hypotension may result if simultaneous antihypertensive medications and treatment of the underlying cause of hypertension are undertaken.

Postoperative Hypotension

As in hypertension, precipitating factors for hypotension must be found and treated. Hypovolemia secondary to inadequate fluid replacement or hemorrhage is the most likely cause of postoperative hypotension (45,46). Others include preoperative and intraoperative anesthetic agents and medications, pain, sepsis, cardiac dysfunction (e.g., dysrhythmias, infarction, failure), pulmonary problems (e.g., inadequate ventilation, emboli, pneumothorax), and electrolyte abnormalities. Postoperative hypotension may have components of hypovolemic, inflammatory, and neurogenic shock. All are treated with fluid replacement to start, usually a crystalloid solution such as normal saline. Colloids are used less frequently, and, if necessary, expanders such as hydroxyethyl starch are used more commonly than albumin, which is expensive, more difficult to obtain, and has some potentially detrimental effects (45,46). If a central venous line is not available to monitor intravascular volume, a fluid challenge consisting of 20 mL/kg of normal saline can be given over a 10- to 15-minute period (45). Clinical examination of the jugular venous pressure can guide replacement, and the infusion may be repeated once or twice. If no improvement is evident, a complete cardiac and pulmonary evaluation is indicated. The patient should have a chest radiograph, ECG, arterial blood gas sample, blood cultures if febrile, and insertion of monitoring catheters (e.g., central venous, arterial, and pulmonary artery lines). Vasopressor medication is indicated if significant hypotension is present (systolic pressure less than 100 mm Hg) and the patient manifests symptoms of decreased profusion, such as obtundation, cardiac

TABLE 3.7 PHARMACOLOGICAL CONTROL OF PERIOPERATIVE HYPOTENSION

Agent	Action	Dosage	Comment
Dobutamine	Beta-adrenergic	2–20 (max 40) mcg/kg/min	Increased cardiac output with minimal effect on heart rate and total peripheral resistance
Dopamine	Primarily beta- and lesser alpha-adrenergic agonist	1–20 (max 50) mcg/kg/min: increased cardiac output without vasoconstriction	Higher than usual doses needed for vasoconstriction and increased cardiac output
Norepinephrine	α_1 and β_1 agonist	Initial 0.5–1 mcg/min then 8–30 mcg/min titrated for response or weight based: 0.01–0.3 mcg/kg/min	Use only when vasoconstrictors are needed to maintain blood pressure
Phenylephrine	Alpha and beta agonist	IV bolus: 0.1–0.5 mg IV infusion: 100–180 mcg/min or 0.5 mcg/kg/min	Neurogenic shock

insufficiency, or decreased urinary output (Table 3.7). Pharmacologic treatment of hypotension is most effective in the neurogenic component of shock, and should be used cautiously since vasoconstriction has a detrimental effect on organs that are already compromised by ischemia (45).

Dysrhythmias

Acute cardiac disease, hypoxia, hypotension, acid–base abnormalities, hypokalemia, and central venous or pulmonary artery catheter stimulation of the heart are common causes of dysrhythmias (47,48). Hypokalemia may be worsened by intraoperative hyperventilation and resultant respiratory alkalosis and by intraoperative fluid replacement and fluid shifts. The underlying causes of cardiac dysrhythmias must be evaluated rapidly and corrected. The goal is to control ventricular rate and maintain normal sinus rhythm.

When a dysrhythmia is present, the clinician must determine if the patient is hemodynamically stable (47–49). Some dysrhythmias, such as nodal rhythm and bradycardia, are common during general anesthesia and usually do not require treatment. Sinus tachycardia is the most common postoperative rhythm abnormality, usually as a physiologic response to surgery, and requires no treatment if the patient is stable. Others can be hemodynamically significant and may be tolerated poorly by a heart already affected by the negative inotropic action of the anesthetic agent. The most obvious example is asystole, which requires cardiopulmonary resuscitation. Cardioversion (100 to 400 J) is the initial immediate treatment of choice for all other dysrhythmias in hemodynamically unstable patients (47). In the hemodynamically stable patient, a full 12-lead ECG should be performed to diagnose the dysrhythmia accurately. The treatment of bradycardia (heart rate less than 60 beats per minute) continues to be atropine, 0.5 mg IV, repeated every 2 minutes as necessary, followed by external or internal pacemaker if the bradycardia is prolonged. For tachydysrhythmias (heart rate greater than 100 beats per minute) with a wide QRS complex greater than 0.08 seconds, ventricular dysrhythmia is suspected and cardioversion is performed, followed by lidocaine, 100 mg IV. For narrow QRS tachyarrhythmias, an IV calcium channel blocker, such as verapamil 1 mg/min or diltiazem 0.25 mg/kg (15 to 20 mg) over 2 minutes repeated at 0.35 mg/kg 10 to 15 minutes later, is given until the heart rate slows, and then digitalization is begun. If the width of the QRS is uncertain, adenosine, 6 mg IV, can be given twice, and if the rate does not slow, cardioversion is performed. With calcium channel blockers, caution must be used in patients who are also taking beta-blockers, as a third-degree heart block may develop, although unusual. As well, with calcium channel blockers, since they are also peripheral vasodilators, hypotension may occur if the patient reverts to sinus rhythm, so adenosine may be preferred (47).

The pharmacologic agents available for tachydysrhythmia have continued to evolve (47,48). Amiodarone is an antidysrhythmic drug that prolongs the myocardial action potential and delays cardiac nodal conduction. It is widely used for treatment and prevention of ventricular tachydysrhythmias and can control atrial dysrhythmias, but does have significant side effects. The loading dose is 150 mg over the first 10 minutes followed by 360 mg for the next 6 hours and 540 mg over the following 18 hours. A maintenance infusion of 0.5 mg/min can be continued for up to 3 weeks, but the patient can also be converted to an oral regimen of 400 to 1,600 mg/day. Magnesium, 100 mg/kg IV over a 1- to 3-hour period, may be effective in the treatment of ventricular dysrhythmias, although the mechanism is unknown. Any of these serious bradydysrhythmias or tachydysrhythmias mandates observation telemetry in the cardiac care unit.

PULMONARY DISORDERS

General Management

Pulmonary problems are the most common complication after surgery (50–52). Anesthesia and surgery have profound effects on pulmonary function. All lung volumes, especially vital capacity and functional residual capacity, are decreased, reducing lung compliance and increasing the work of breathing. The result is alveolar hypoventilation with atelectasis, VQ abnormalities, and hypoxemia. Extravascular lung water also may be increased from increased hydrostatic pressure secondary to fluid overload and low plasma oncotic pressure. If the pulmonary capillary endothelium also is damaged from exposure to toxic products from injury, infection, or the surgical procedure, increased capillary permeability may increase lung extravascular water. In otolaryngologic procedures, impaired laryngeal protective mechanisms, airway edema, and foreign bodies such as blood clots may promote aspiration.

Treatment is initiated in the preoperative period with preventive measures and identification of the patients who may be at a higher risk for pulmonary problems (50–52). Historic symptoms, such as dyspnea on exertion, cough, sputum production, and cigarette smoking, indicate the need for further evaluation. The physical examination should include auscultation during maximal inspiration and forced expiration. Observation of the patient climbing stairs remains a valuable adjunct to clinical estimation of pulmonary and cardiac reserve. The preoperative chest radiograph can demonstrate pathology, but it is more important when used for postoperative comparison. A preoperative chest radiograph in asymptomatic patients is recommended for known pulmonary or cardiac disease, age older than 40 years, high risk for postoperative pulmonary complications, and a positive tuberculin test or high risk for unsuspected tuberculosis. Pulmonary-function tests can give the clinician an idea of the degree of alveolar ventilation and the ability to clear secretions in the

postoperative period. This is especially important in major head and neck resections in which aspiration may be common. The best overall predictor of postoperative pulmonary difficulties may be the maximal voluntary ventilation (MVV) test, which is the largest volume that can be breathed by voluntary effort per minute, extrapolated from rapid breathing into a spirometer during a 15-second interval (50). This test measures lung function, compliance of the chest wall, strength of the respiratory muscles, and patient motivation and ability to cooperate. An MVV value of less than 50% of predicted value has been correlated with postoperative pulmonary complications.

Preoperative arterial blood gases provide mainly a comparison for postoperative measurements, are not predictive of postoperative pulmonary insufficiency, and are not routinely indicated. Any patient with arterial oxygen tension less than 60 to 70 mm Hg usually has a significant VQ mismatch. An arterial carbon dioxide tension greater than 45 mm Hg indicates significant alveolar hypoventilation and is associated with an increased incidence of postoperative complications. Reversible causes, such as bronchospasm or bronchitis, should be corrected preoperatively.

Preventive measures are begun as soon as a decision to operate is made and are carried through the entire postoperative course. Predisposing factors for lung complications, such as smoking or obesity, and underlying pulmonary conditions, such as chronic bronchitis, chronic obstructive pulmonary disease, and reactive airway disease, are corrected insofar as possible before surgery. Ideally, pulmonary exercises that will be performed postoperatively should be practiced before surgery. These include deep breathing and the use of incentive spirometry. The main thrust of postoperative care is deep-breathing exercises to enhance alveolar aeration and ventilation. Unless secretions are a major problem, coughing may not need to be encouraged and may be detrimental in skull-base procedures with an increased chance of a spinal fluid leak. Mechanical assistance such as intermittent positive pressure breathing (IPPB) can be used in the weak patient but are not usually necessary. Bronchodilators are used in chronic obstructive lung disease.

The choice of anesthesia is important. Although local anesthesia may seem preferable, general endotracheal anesthesia gives the best control over the airway. Maintaining a large tidal volume of 10 to 15 mL/kg and slow respiratory rate with frequent sustained inflation to 20 mL/kg or to an airway pressure of 30 cm H_2O should be performed to prevent alveolar collapse. Intravenous crystalloid solutions should be given conservatively and blood or plasma replacement products should be given with large blood and plasma losses to help maintain normal intravascular colloid pressure and prevent pulmonary edema. Diuresis is indicated for significant fluid overload.

Preventive measures should be continued in the postoperative period. The endotracheal tube should be kept in place as long as necessary to maximize alveolar ventilation. Immediately after endotracheal tube removal, deep-breathing exercises, clearance of respiratory secretions, and frequent turning of the patient are begun. Supplemental oxygen should only be used for a few hours, unless dictated by arterial blood gases, in order to avoid respiratory suppression of deep breathing (52). If the patient is unable to perform maximal inhalation exercises or incentive spirometry, continuous positive airway pressure or IPPB may be of help in preventing atelectasis.

Management of Postoperative Pulmonary Insufficiency

Dyspnea, tachypnea, tachycardia, and cyanosis in the postoperative period are signs of acute pulmonary insufficiency (51,52). Atelectasis, bronchospasm, pulmonary edema, and aspiration are the most common causes. Exacerbations of preexisting pulmonary problems, mechanical limitations of breathing, acute bronchospasm, pulmonary embolization, congestive heart failure, and hypovolemia also should be considered. In head-and-neck procedures, mechanical limitations to breathing may be caused by gastric distention, pneumothorax, aspiration, or phrenic nerve injury with hemidiaphragmatic paralysis, in addition to any laryngeal or pharyngeal manipulation. If pulmonary insufficiency is suspected, supplemental oxygen should be given immediately to increase oxygen saturation to greater than 90% on pulse oximetry while a pertinent history, physical examination, arterial blood gases, and a chest radiograph are obtained. The patient should be in a comfortable sitting position. Nasogastric tube placement is considered to empty the stomach of any further gastric acid. Bronchospasm may be present and respond to bronchodilators.

Treatment of atelectasis is aimed at re-expanding the collapsed segment. Deep-breathing exercises, incentive spirometry, continuous positive airway pressure, and IPPB can be used. Adequate pain medication should be provided to promote mobility and deep breathing. Increased hydration, mist, nebulized bronchodilators, and mucolytic agents should be given through the airway to liquefy thickened secretions that may be blocking the involved bronchus. Coughing is not helpful in preventing postoperative pulmonary problems. Paradoxically, coughing does not clear mucus from collapsed airways because no air is distal to the mucous plug. Immediate treatment consists of mechanical removal of any foreign substance from the upper airway. Tracheal suction may be successful in removing retained secretions but should be performed only if deep breathing is not successful and then with caution because it may produce increased vagal tone and hypoxemia. Oxygen can be connected to the nasotracheal catheter and 5 mL of saline can be injected through the catheter to help liquefy secretions and facilitate aspiration through the catheter. Suction should be applied for no longer than 10 seconds before oxygen flow is resumed to prevent cardiac dysrhythmia. During tracheal suctioning, ECG monitoring should be

performed with atropine available for bradycardia. Flexible bronchoscopy allows direct visualization of the bronchial tree, removal of debris, and culture of sections. The same precautions as for tracheal suctioning are used. If adequate ventilation (respiratory rate less than 30/minute and oxygen saturation greater than 92%) cannot be restored by these methods, endotracheal intubation and mechanical ventilation are indicated. Supplemental oxygen should be kept as low as possible to avoid nitrogen displacement from alveoli and exacerbation of atelectasis.

Pulmonary edema is caused by an increase in lung water, and treatment is directed at decreasing the excess water (51,52). Treatment is directed toward decreasing extracellular fluid, decreasing pulmonary capillary bed hydrostatic pressure, and increasing plasma oncotic pressure. Furosemide is the diuretic of choice because it promotes venodilation and diuresis. Treatment in younger or previously healthy patients may simply involve fluid restriction and the use of diuretics as necessary. For patients with cardiopulmonary or renal disease, dobutamine, dopamine, or both may be required for low cardiac output and to increase renal perfusion. Nitroprusside may be necessary for patients with high systemic vascular resistance to reduce the cardiac afterload. Intravenous nitroglycerin may help patients who have coronary insufficiency. If hypoxemia or hypercapnia persists after these measures, ventilatory support may be necessary.

A flow-directed pulmonary artery catheter can help distinguish high- from low-pressure pulmonary edema. Cardiogenic pulmonary edema, on the one hand, is usually associated with a pulmonary artery wedge pressure greater than 25 mm Hg. In cardiogenic pulmonary edema, interstitial edema progresses to alveolar edema. Adult respiratory distress syndrome, on the other hand, is manifest as pulmonary edema in the presence of normal pulmonary artery wedge pressure. Lung damage is indirect and usually caused by infection, inflammation, or tissue destruction elsewhere in the body. It manifests as severe hypoxemia and decreased lung compliance, and it shows diffuse bilateral pulmonary infiltrates on chest radiograph. Management is directed at treating the underlying cause, with specific attention to aggressive antibiotic treatment of presumed infection. Severe hypoxemia and hypercapnia may need mechanical ventilation with positive end-expiratory pressure. Inspired oxygen content should be kept low to minimize oxygen toxicity while maintaining the hemoglobin oxygen saturation above 90%. Intravascular volume is kept low; dobutamine or dopamine may be needed for inotropic support.

GASTROINTESTINAL DISORDERS

Stress Ulcers

In patients who do not have a history of peptic ulcer disease, the most common cause of postoperative upper gastrointestinal bleeding is stress ulceration of the gastric mucosa (53). These ulcers develop as a result of trauma, surgery, medications such as corticosteroids or NSAIDs, or the stress associated with severe illness. The ulcers are usually painless, and the clinical presentation may be limited to a bloody aspirate from an indwelling nasogastric tube, melena, or an unexplained decrease in hematocrit. Predisposing conditions include coagulopathy and mechanical ventilation (54).

The main thrust of management should be prevention, and prophylactic measures should be considered in all major head-and-neck cases. Prevention of stress ulceration is aimed at reducing gastric acidity (above pH of 4 to 5), which may be accomplished by histamine (H_2)-receptor antagonists, cytoprotective agents, the mucosal protective effect of early enteral feedings, or antacids. Currently the preferred method is with proton-pump inhibitors (PPIs) such as omeprazole, which can be given IV or an oral dose of 40 mg, b.i.d (53–55). The IV dose of H_2-antagonist cimetidine is 50 mg/h or 300 mg every 6 hours, and the dose for ranitidine is 6.25 mg/h or 50 mg every 8 hours for the continuous or bolus injections, respectively. A continuous IV infusion may be more effective than bolus injections. The alteration in gastric pH caused by H_2-receptor antagonists and PPIs may predispose to gastric bacterial colonization and nosocomial pneumonia. Cytoprotective agents, such as sucralfate suspension, maintain the integrity of the stomach mucosal barrier without lowering pH. Sucralfate must be activated by gastric acid so cannot be used with PPI, H_2 blockers, or antacids (53). The dose is 1 g in 10 to 20 mL of sterile water infused into the stomach every 6 to 8 hours via nasogastric tube. Antacids are effective, but must be taken every 1 to 2 hours. If *Helicobacter pylori* is present, antibiotics should be given.

If stress ulcers develop, treatment methods are similar to those used in prophylaxis. Basic resuscitation is started, and blood tests sent for CBC and coagulation studies. Emergencies (e.g., hypovolemia) must be managed immediately with fluid or blood replacement. In the bleeding patient, an IV PPI, such as pantoprazole, 40 to 80 mg every 12 hours, is given. A large-bore nasogastric tube can be placed to decompress the stomach, to provide access for saline lavage, and to examine gastric aspirate. Esophagogastroduodenoscopy is the procedure of choice, gives direct visualization of the gastric mucosa for diagnosis, and allows an attempt at endoscopic control of hemorrhage by such methods as thermal coagulation or laser photocoagulation. If no site of bleeding is seen endoscopically, arteriography is performed to determine the bleeding site. Arterial embolization or selective injection of vasopressin into the left gastric artery has been used. Barium studies of the bowel are quite common, but the barium may interfere with tests such as CT or arteriography. Surgical intervention may be necessary for patients with persistent bleeding or ulceration despite conservative therapy, although the mortality of gastric resection for postoperative hemorrhage is high.

Adynamic Ileus

Ileus is much more common after abdominal procedures than after head-and-neck procedures. The otolaryngologist, however, must certify that intestinal motility exists before beginning postoperative feeding, especially hyperosmolar tube feeding. Adynamic ileus should be suspected in any patient with obstructive symptoms of constipation, prolonged vomiting, abdominal pain and distention, or an absence of bowel sounds (55). Abdominal upright and supine radiographs show a diffuse gas pattern and distended loops of bowel. The most common cause is the perioperative administration of pharmacologic agents, including anesthetic agents, opioids, sedatives, adrenergic agonists, anticholinergics, calcium channel blockers, and antihistamines. The differential diagnosis must include hypokalemia, distal obstruction (e.g., fecal impaction, neoplasm), sepsis, and an acute abdominal event, such as exacerbation of diverticulosis. Endoscopy or contrast enema may be necessary to rule out bowel obstruction. The treatment is directed at the underlying cause. The patient usually responds to supportive measures of avoidance of oral intake, discontinuation of narcotics, administration of intravenous fluids, correction of electrolyte abnormalities, and nasogastric suction. Sympathetic blockade or parasympathetic stimulation with bethanechol, neostigmine (2 mg IV over 3 to 5 minutes), or metoclopramide is rarely used and is contraindicated if a mechanical obstruction is present. Erythromycin, 200 mg IV, stimulates upper gastrointestinal motility and is an alternative (55). With these measures, the ileus usually resolves within a period of several days.

Diarrhea

The most significant exudative diarrhea is antibiotic-associated diarrhea and colitis (54,55). The severity of antibiotic-related diarrhea varies from mild diarrhea to pseudomembranous colitis with severe systemic manifestations. Antibiotics frequently used in otolaryngology patients may precipitate the syndrome. Clindamycin and ampicillin are the most common causes, but cephalosporins, erythromycin, penicillin, and trimethoprim–sulfamethoxazole also have been implicated. With persistent diarrhea, a stool examination is paramount. Fecal leukocytes suggest a bacterial infection or an antibiotic-associated pseudomembranous colitis. The stool should be evaluated for enteric pathogens, *Clostridium difficile*, and intestinal parasites (if the patient has been to an endemic area). More than 90% of patients with antibiotic-associated pseudomembranous colitis test positive for *C. difficile* toxins.

Management is both supportive and specific. Fluid and electrolyte balance must be monitored closely and may require measurement of electrolyte levels in stool samples. Potassium and bicarbonate losses may be large and may require IV replacement with up to two ampules of sodium bicarbonate in each liter of 5% dextrose in water. If cessation of the causative antibiotic does not relieve diarrhea, then treatment with appropriate antibiotics is guided by stool culture. Metronidazole (500 mg orally three times daily) is given for 10 to 14 days for patients who tolerate oral intake. Recurrences are common and are treated with a second course of metronidazole. Vancomycin (125 to 500 mg, PO, q.i.d.) is reserved for resistant bacteria or for patients who do not tolerate metronidazole. Intravenous metronidazole is less effective but can be used in patients who cannot take enteric medications. Intravenous vancomycin is not effective, but intracolonic irrigation has been tried. Antiperistaltic medicines should be avoided because decreased intestinal motility promotes bacterial overgrowth. Other causes of diarrhea such as osmotic, secretory, and altered intestinal motility, such as "bacterial overgrowth syndrome," should be considered if resolution is not prompt.

RENAL DISEASE

Two considerations are important in the perioperative management of renal disease. The first is treatment of patients with known renal disease, and the second is the prevention or recognition of acute renal failure in the postoperative period (18,23,31).

Chronic Renal Failure

Dialysis (renal replacement therapy) must be continued before and after surgery to minimize uremic complications such as acid–base, fluid, and electrolyte imbalances (56–58). In the elective situation, the patient is dialyzed on the day before and the day after surgery. The surgeon must take into account the need for heparin as an anticoagulant during dialysis, but this effect is minimal in 6 to 8 hours.

Other problems specific to chronic renal failure should be addressed. Baseline hematocrits in the 20% to 25% range should be adequate for surgery unless large blood losses are expected. Platelet dysfunction in renal disease is corrected only partially by dialysis. For patients with active bleeding secondary to uremic platelet dysfunction, administration of DDAVP at a dose of 0.3 mg/kg or platelet transfusion should be considered. Hypertension should be controlled with diuretics and dialysis, if necessary, for restoration of normal intravascular volumes.

An effort should be made to avoid medications with known renal toxicity, including anesthetic agents. Some volatile anesthetic agents, such as enflurane, produce fluoride and can lead to fluoride-induced kidney damage. Halothane can be used as an inhalation agent and propofol can be used as an infusion agent for general anesthesia (58). The neuromuscular blockers and anticholinesterases, especially succinylcholine, may potentiate hyperkalemia and acidosis.

Intraoperatively, the goal should be to prevent further kidney damage (56–58). An effort should be made to optimize renal profusion by correcting volume deficits and maintaining adequate cardiac output. In patients who are not anuric, urinary output should be maintained at a level of at least 0.5 mL/kg/h. Renal blood flow can be augmented with low-dose dopamine (1 to 5 mg/kg/min). Diuresis can be stimulated with mannitol or a loop diuretic like furosemide in an effort to maintain preoperative urine outputs. Urgent treatment of hyperkalemia can be accomplished with initial infusion of calcium chloride, 5 to 10 mL of 10% solution; sodium bicarbonate, 44 mEq in 2 minutes as needed for associated metabolic acidosis; and insulin, 10 U over a 30-minute period, concurrently with dextrose, 250 mL of 20% solution.

After surgery, fluids, electrolytes, acid–base balance, and hematocrit should be watched closely. In severe abnormalities, urgent hemodialysis may be necessary despite the need for heparin. In chronic renal failure patients, postoperative congestive heart failure may develop secondary to ischemic heart disease or hypotension secondary to volume depletion, decreased cardiac output, or abnormal receptor function. Nutritional support with a diet high in carbohydrates and essential amino acids is important. Adequate caloric intake (1,800 to 2,500 kcal/day or 35 kcal/kg/day) is provided to avoid endogenous protein catabolism. Protein is restricted to 1.0 to 1.4 g/kg daily of high-biologic-value protein. Prophylactic antibiotics and careful wound management are indicated because of decreased immune function.

Acute Renal Failure

Acute renal failure, also termed "acute kidney injury" (AKI), is an acute decrease over hours to days in renal function and glomerular filtration rate (GFR) with a rise in creatinine of 0.5 mg/dL in normal patients or a 25% rise of creatinine in preexisting renal disease. In hospitalized patients, even a rise of 0.3 mg/dL is significant (56). Diminished urine output (i.e., <0.5 mL/kg/h or <400 mL/day in adults, and <1.0 mL/kg in children weighing <10 kg) should prompt an investigation to eliminate renal causes. Difficulty in voiding, with resultant urinary retention, may be caused by perioperative medication. Placement of a bladder catheter may be necessary to relieve urinary retention and to monitor adequate urinary output. If a postrenal obstruction is suspected, ultrasonography is performed. Continued low urinary output through the bladder catheter demands immediate action in an attempt to prevent renal damage and acute renal failure (56–58). Clinical assessment should be used to differentiate between hypovolemia and decreased cardiac function. Prerenal hypovolemia or hypotension is the most common cause of low urine volume in head-and-neck surgery patients. The urine is low in volume, sodium, and chloride and high in osmolarity. Urine sodium is less than 20 mEq/L in prerenal hypovolemia and greater than 40 mEq/L in intrinsic renal failure. The fractionated urinary excretion of sodium (FE_{NA}), a similar measure, is less than 1% in prerenal failure and greater than 3% in renal causes, whereas values between 1% and 3% suggest a combination of prerenal and intrinsic renal failure. In hypovolemia, treatment should be directed toward increasing renal perfusion by rapid infusion of intravenous fluids to increase the central venous pressure to at least 10 mm Hg. The intravenous fluid bolus should be 500 to 1,000 mL of normal saline. Blood may be used for this bolus if significant blood loss occurred during surgery. Controversy exists concerning the use of diuretics and osmotic agents such as mannitol because they have not been shown to decrease the mortality from renal failure. Administration of these agents hinders the use of urine volume and electrolytes, described earlier, as a measure of renal function for at least 24 hours. However, diuretics can convert an oliguric to a nonoliguric renal failure, which may have a higher survival rate. If diuretics are used, 40 mg of furosemide is administered intravenously with observation for increased urinary output over the next 60-minute period. In the volume depleted with prerenal failure, NSAIDs, which inhibit the vasodilatory effects of prostaglandins, ACE inhibitors, and angiotensin receptor blockers, which can cause efferent arteriolar dilation and drop in GFR, and nephrotoxic medications such as aminoglycosides, should also be avoided (57). Dopamine, which improves renal blood flow, has not been found to prevent the development of AKI (56).

The most common postoperative intrinsic renal cause of acute renal failure is acute tubular necrosis secondary to ischemia or nephrotoxicity. It is characterized by oliguria, an increasing serum creatinine, and examination of urinary sediment demonstrates classic pigmented granular casts. Urinalysis demonstrates a hypo-osmolar urine with a high sodium and FE_{NA} content and a low urinary-to-plasma creatinine ratio. After a tentative diagnosis of acute tubular necrosis or other renal cause of acute renal failure is made, baseline laboratory and clinical values, such as body weight, blood pressure, chemistry and hematologic profile, urinary chemistry and sediment examination, and consideration for renal imaging studies or ultrasonography, should be performed. Early nephrology consultation should be obtained. Conservative management may be successful with a high-carbohydrate and low-protein diet, fluid and electrolyte management, and careful reevaluation of all medications. If hyperkalemia, volume overload, acidosis, or uremia develops, dialysis may be necessary.

NEUROPSYCHIATRIC PROBLEMS

Postoperative Seizures

The goals of therapy for postoperative seizures are to control the seizure and to determine the underlying cause (59,60). Typical seizures for patients with known seizure

disorders may simply require supportive measures and continuation of anticonvulsant medications. Atypical seizures in a known seizure patient or new seizures in a previously asymptomatic patient require immediate investigation for a treatable underlying cause.

Metabolic imbalances such as hyperglycemia or hypoglycemia, hypoxia, acid–base disturbances, hypernatremia or hyponatremia, or other electrolyte abnormalities may cause seizures. Head trauma, fever (especially in children), stroke, subarachnoid hemorrhage, central nervous system infections, drug and alcohol withdrawal, cardiac dysrhythmias, hypotension, and certain drugs and toxins can precipitate a seizure. Overdosage of cocaine and local anesthetics like lidocaine are of particular concern to the otolaryngologist. The patient's history should highlight any previous neurologic disease, possible drug reactions, and fluid and electrolyte abnormalities. Complete general and neurologic and physical examinations should be performed, with special attention to any seizure sequelae such as trauma, aspiration, or rhabdomyolysis. Characteristics of the seizure also should be noted. If the seizure is self-limited, the laboratory evaluation should include a rapid glucose determination, CBC, blood chemistries including calcium and magnesium, oxygen saturation, and ECG. If an immediate cause for the seizure is not found, then an electroencephalogram, lumbar puncture, and an imaging study of the head with contrast are performed.

Status epilepticus is the condition of continuous or repeated seizures, usually lasting longer than 5 to 20 minutes, and is a true medical emergency (59,60). More prolonged seizures tend to become more refractory to treatment (60). The condition produces acidosis, hypotension, relative hypoglycemia, rhabdomyolysis, autonomic and cardiovascular dysfunction and may produce cerebral damage from local hypermetabolism and prolonged hypoxia. An abbreviated search for underlying causes is important, but the primary goals are to stop the seizure, maintain the airway and ventilation, avoid hypoxia, and avoid complications, such as an injury to the operative site. An intravenous catheter is placed, and blood should be drawn for the aforementioned tests. Serum anticonvulsant drug levels and arterial blood gases also should be tested. Metabolic and ventilation abnormalities should be corrected. Immediate treatment can be started with empiric IV injection of thiamine, 100 mg, and a glucose injection, 50 mL of 50% dextrose, should be given if the fingerstick glucose is low or not available. Pharmacologic control is obtained with benzodiazepines, phenytoin, and barbiturates (Table 3.8). Because high doses may be required, the clinician should be ready to support ventilation. Intubation may be necessary to protect the airway. The antiseizure duration of action of diazepam is relatively short: about 20 minutes. Lorazepam also may be used, and the duration of action is somewhat longer. Phenytoin should be used in addition to the benzodiazepines and will be used as the long-term therapy. No significant central nervous system depression occurs with phenytoin, but rapid administration may cause cardiovascular toxicity. The longer-duration action of phenytoin supplements the initial control obtained by the benzodiazepines. Fosphenytoin, expressed as phenytoin equivalents (PEs), is preferred to phenytoin for parenteral injection because of less venous irritation. Phenobarbital also can be used if phenytoin is not tolerated or is contraindicated, but it leads to depression of consciousness and respiration. Blood levels should be checked to monitor treatment levels for phenytoin and phenobarbital. For a patient refractory to IV medications, phenobarbital coma, propofol, or other general anesthesia with neuromuscular blockade may be used to control the status epilepticus.

TABLE 3.8 PHARMACOLOGIC MANAGEMENT OF STATUS EPILEPTICUS

Agent	Dosage
Diazepam	
Adults	IV bolus of 5–10 mg at 1–2 mg/min or 0.15 mg/kg at 5 mg/min (max 30 mg)
Children	1 mg/y of age to total dose of 5–10 mg
Lorazepam	2–4 mg IV, 2 mg/min, q5–10 min, usual maximal dose: 8 mg
Phenytoin	
Adults	Loading dose of 15–20 mg/kg at 30–50 mg/min (max dose 30 mg/kg)
Children	Loading dose of 10–20 mg/kg at 0.5–1.5 mg/kg/min
Phenobarbital	Loading dose of 10–20 mg/kg IV (initial bolus 200–300 mg), repeat in 20 min
Propofol	1–2 mg/kg loading dose, then 1.5–10 mg/kg/h (intubation required)
Supportive	
Glucose	
Adults	50 mL of a 50% solution
Children	1–2 mL/kg of a 25% solution
Thiamine	100 mg IV
Calcium gluconate	1–2 amps for recent thyroid or parathyroid surgery

Myasthenia gravis: Multiple factors may increase muscular weakness for patients who have myasthenia gravis in the perioperative period (61). Anticholinesterase preparations like pyridostigmine or neostigmine should be maintained preoperatively and reinstituted on the first postoperative day. For patients who are unable to resume postoperative oral or tube feedings, neostigmine and pyridostigmine can be given as a continuous IV infusion. Certain medications, including quinidine, curare, lithium, beta-adrenergic blockers, phenytoin, and aminoglycoside antibiotics, may increase weakness and should be avoided. Vital capacity can be used to monitor pulmonary function. Increased weakness of the respiratory muscles may be caused by surgical stress and may require assisted

ventilation or tracheostomy if vital capacity falls to 15 mL/kg (62). Corticosteroids, immunosuppressive agents such as azathioprine or cyclosporin, or plasmaphoresis is used to supplement the benefit of anticholinesterases, but the ultimate therapeutic benefit in myasthenia gravis may not be seen for several weeks or months.

Cognitive impairment: Cognitive function or general mental status may decrease after surgery (63,64). Patients aged over 60 years or who have addictions to alcohol or drugs, major organ system disease, preexisting or family histories of psychosis, or even auditory or visual impairment are predisposed to perioperative cognitive impairment. Even a simple otologic procedure with a mastoid head dressing may prevent the use of hearing aids and glasses and add to disorientation. The entire hospital environment of sensory overload, sleep deprivation, anxiety, and pain contribute to disorientation and decreased cognitive function. Underlying medical conditions should be treated promptly, routine medications continued, excessive use of narcotics or benzodiazepines (e.g., diazepam) avoided, and a comfortable hospital routine established.

An attempt should be made to classify the type of cognitive impairment. Delirium should be differentiated from dementia, depression, mania, and other organic brain disorders. Dementia is a clinical syndrome that has a protracted course and is characterized by loss of cognitive abilities, personality disorganization, and decreased ability to perform daily activities without disturbance of consciousness. It is usually present in the elderly (e.g., Alzheimer disease) with a presumed organic cause. Depression, mania, and other functional disorders (e.g., schizophrenia) are true psychiatric disorders. The otolaryngologist is more likely to see delirium, a transient organic mental disorder characterized by the acute onset of impairment in attention and arousal. Restlessness, insomnia, irritability, frightening dreams, difficulty in thinking, disturbed consciousness, urinary incontinence, focal neurological signs, nystagmus, and loss of motor coordination all are seen in delirium. Causes of delirium can include drug intoxication, drug withdrawal (especially alcohol, discussed below in a separate section), metabolic disturbances, acute cerebral disorders (e.g., stroke, transient ischemic attack), infections, hemodynamic disturbances (e.g., hypovolemia, congestive heart failure), respiratory disorders, nutritional and vitamin deficiencies, and trauma. Psychiatric consultation may be necessary to help differentiate the type of cognitive impairment and guide the discovery of underlying causes.

Communication with, and management of, the patient in delirium is difficult. Agitation is pronounced. Conservative therapy can include removal of known precipitating factors, orientation to the environment with special attention to the use of a hearing aid and glasses, and pain control. If reassurance is not sufficient, medications may be necessary. Haloperidol is most often used, starting with 0.25 mg, and repeated every 30 minutes up to a loading dose of 5 mg/day. Atypical antipsychotic agents, such as risperidone or quetiapine, may have fewer extrapyramidal and sedative side effects. The anticholinesterase inhibitor donepezil may be useful with patients with delirium coexisting with dementias such as Lewy body (64). Recovery from postoperative delirium can be prolonged with some lasting effects.

GENERAL CONSIDERATIONS

Postoperative Fever

Body temperature is set by the thermoregulatory center in the anterior hypothalamus. In hyperthermia, such as heat stroke or malignant hyperthermia of anesthesia, the thermal-regulation mechanisms fail, and heat production exceeds heat loss. In a patient with fever, cytokines from mononuclear cells, important in the early-phase response to infection and inflammation, act directly on the hypothalamus to increase the "thermal set point." When the thermal-regulation set point is elevated in fever, this increased body temperature is maintained by limiting heat loss from the body by vasoconstriction and increasing heat production by mechanisms such as shivering. This explains why patients with new extremely elevated body-set temperatures feel cold even in the environment of a mildly elevated temperature. If the current body temperature is less than the elevated set point, the patient feels cold, vasoconstricts, and shivers in an effort to raise body temperature to the new temperature set point.

Although common, inflammation and infection are not the only causes of postoperative temperature elevation (65,66). Numerous noninfectious factors may cause temperature elevation, especially in the first 48 to 72 hours after surgery (Table 3.9). Infectious causes of fever usually occur 3 to 7 days after surgery, somewhat later than noninfectious causes (Table 3.9). Sinusitis and otitis may develop in the postoperative period, either from primary head-and-neck surgery or from blockage caused by nasal tubes. The otolaryngologist may be consulted by other services to exclude these common and potentially serious postoperative infections.

Evaluation of the postoperative fever should include a complete history and physical examination rather than a protocol format of blindly ordering cultures from the most common infectious sites (65,66). The first step should be a repeated rectal temperature to evaluate core body temperature. It is difficult to give an absolute definition of fever, but any elevation of 1 °C to 2 °C that occurs over a short period or an absolute elevation over 38.5 °C (101.3 °F) should be investigated. In the physical examination, special attention should be paid to the wound, chest, and signs of phlebitis in extremities. The following procedures should be performed if no obvious site is found: a leukocyte count and urinalysis; Gram stain of sputum, urine, and wound exudate; cultures of blood, sputum, urine, wound, and blood; chest radiograph; and removal and culture of intravenous

TABLE 3.9 POSTOPERATIVE CAUSES OF FEVER

Noninfectious causes
- Hematoma and tissue trauma
- Atelectasis
- Nonseptic phlebitis and DVT
- Drug or anesthetic allergies
- Transfusion reactions
- Presence of drains or catheters

Less common noninfectious causes
- Activation of inflammatory disease (lupus, rheumatoid arthritis)
- Endocrine excess (thyroid storm)
- Hypothalamic abnormalities

Infectious sites
- Wound
- Urinary tract
- Respiratory
- Intravascular catheter and site
- Infected prosthesis or foreign body
- Meningitis (especially in skull-base surgery)
- Sinusitis or otitis media
- Diarrhea: antibiotic-associated colitis

catheters. After neurotologic procedures, consideration should be given to examination and culture of spinal fluid. In general, the history, physical examination, and a few selected tests should suffice to evaluate the febrile patient. The clinician should not forget that unexplained fever in the postoperative period is common and does not mean an infection is impending.

Nosocomial infection, defined as an infection acquired in the hospital, is a major concern for the otolaryngologist. Surgical site infection (SSI) is the third most common type of nosocomial infection, and is defined as an infection within 30 days of surgery, or within 1 year of an implanted prosthesis (67–69). The use of prophylactic antibiotics for prevention of SSI has evolved to a single dose treatment, given within 30 to 60 minutes prior to the surgical incision (65–68). Cefazolin, at a simplified preoperative dose of 2 g for all adult patients, is the current recommended antibiotic, and may need to be repeated every 4 hours or for extensive blood loss. Antibiotics should not be continued longer than 24 hours, and there is good evidence that any prophylactic prevention of SSI for the most common bacteria is achieved in the first few hours. For patients with a penicillin allergy, clindamycin is the alternative, and metronidazole is a consideration for anaerobic coverage (65–67). The risk of infection in most head-and-neck surgery is low, and prophylactic antibiotics may not be needed except for cases that will last longer than 2 hours or where the oropharyngeal area will be entered or a prosthesis placed. Special circumstances include the patient who has cultured positive for methicillin-resistant staphylococcus, where intranasal mupirocin may be given. Additional measures to help prevent infection include glucose control, avoidance of hypoxemia, maintenance of normothermia, use of hair clippers instead of blade shaving, and cleansing with antibacterial solutions such as chlorhexidine (not approved for ears or contact with meninges).

Treatment is based on the underlying cause and an understanding of the physiology of temperature regulation. SSIs should be treated with drainage first, cultured, and appropriate antibiotics if necessary. Pulmonary atelectasis requires aggressive pulmonary toilet, and in the event of progression to pneumonia, antibiotics and possible bronchoscopy are indicated. If no obvious cause is discerned or while waiting for laboratory confirmation, treatment is directed toward lowering body temperature and the comfort of the patient. Mild temperature elevations are usually well tolerated and do not require specific treatment. Elevations over 39°C (102.2°F) increase the body's metabolic demands and may be accompanied by tachypnea, tachycardia, and malaise. In this situation, the body temperature set point should be reduced by antipyretics (aspirin or acetaminophen, PO or rectally, 325 to 650 mg, every 4 hours, is the preferred medication). Other treatments, such as removing bed covers, cool or ice-water sponge baths, reducing room temperature, or increasing air flow over the patient add a cold stress to the patient and are not necessary unless the core body temperature exceeds 40°C (104°F). If the body set point is not reduced by the antipyretics before these adjunctive measures are used, counterproductive vasoconstriction and shivering will attempt to maintain the elevated temperature set point. Meperidine, currently not given for postoperative pain, is a preferred medication for shivering, although benzodiazepines are also effective. Other abnormalities, such as electrolyte imbalances, should be corrected, and an adequate supply of glucose to meet the higher metabolic demands of the fever should be administered. In life-threatening elevations of body temperature (41°C or 105.8°F), special attention must be given to the cardiorespiratory reserve. Rapid cooling of the body temperature can be achieved in this situation by placing the patient in an ice bath or even on partial cardiopulmonary bypass with a heat exchanger if necessary.

Malignant Hyperthermia

Malignant hyperthermia occurs in anesthetized patients and is, if untreated, highly lethal. Because a genetic predisposition exists, all preoperative patients should be asked whether any family relative has had the condition. In malignant hyperthermia, abnormal sarcoplasmic reticulum release of calcium in skeletal muscle occurs, causing a sustained contraction with increased oxygen consumption and heat production. Patients with the condition are sensitive to the inhalation agents (e.g., halothane or enflurane) and the muscle relaxant succinylcholine chloride.

TABLE 3.10 TREATMENT OF MALIGNANT HYPERTHERMIA

Signs
- Sharp increase in core body temperature
- Cardiac arrhythmias
- Excessive bleeding
- Rise in end-tidal carbon dioxide concentration

Management
- Stop succinylcholine and inhalation agent immediately
  - 100% oxygen
- Dantrolene sodium, 2.5 mg/kg IV q5–10 min to max dose of 10 mg/kg
- Sodium bicarbonate, 1–2 mEq/kg IV for acidosis (monitor blood gases)

Support therapy
- Remove drapes
- Lower core temperature with iced saline (IV, rectally, or intragastrically)
- Application of ice to exposed body parts
- Watch for hyperkalemia, acidosis, myoglobinuria, arrhythmias, and posttreatment hypothermia

Signs usually occur shortly after the onset of anesthesia (Table 3.10). The specific treatment is dantrolene sodium, which inhibits the release of calcium in the endoplasmic reticulum of the skeletal muscle. Marked hyperkalemia from potassium released from muscle cells, acidosis, and malignant dysrhythmias may need urgent treatment.

TABLE 3.11 PHARMACOLOGIC MANAGEMENT OF POSTOPERATIVE PAIN

Drugs	Initial Dose
Opioids	
Morphine (agonist)	IV: 2.5–10 mg, duration 3–4 h Continuous IV infusion: 3 mg/h (loading dose 5–10 mg) PCA: Lock out 5–10 min Adults: 0.5–3.0 mg Children: 0.01–0.03 mg/kg, max 0.15 mg/kg/h
Hydromorphone (agonist)	IV: 1–2 mg, q4-6h PCA: Lock out 5–10 min Adults 0.05–0.25 mg Children: 0.003–0.005 mg/kg, max 0.02 mg/kg/h
Buprenorphine (partial agonist)	IV/IM: 0.3 mg, repeat in 30–60 min, then q4-6h
Tramadol	PO: 50–100 mg q4-6h, max daily 400 mg Nonurgent: initial 25 mg/d, increase 25 mg/every 3rd day
Nonsteroidal anti-inflammatory drugs	
Ibuprofen	200–400 mg, PO, q6h
Indomethacin	50–100 mg, PO, q6-8h
COX-2 inhibitor	
Celecoxib	400 mg initial dose, then 200 mg twice daily
Other	
Acetaminophen	500–1,000 mg, PO, q6h (max daily dose: 4,000 mg)

Postoperative Pain

Postoperative pain is often inadequately controlled as a result of a variety of factors, including fear of side effects (e.g., respiratory depression, nausea), fear of addiction, or failure to give medicine as prescribed. The otolaryngologist should give consideration to pain control in both the preoperative and postoperative periods. A complete explanation of the procedure to the patient and a discussion of the plan for pain control can alleviate anxiety that contributes to pain. Continuing concern and reassurance postoperatively also are important in the psychologic management of pain relief (69).

Pharmacologic treatment of postoperative pain revolves around the administration of systemic opioids (29,69) (Table 3.11). Patient-controlled analgesia (PCA) is a safe and reliable method of delivering postoperative pain relief without the delay associated with formulating IV or IM injections. Morphine remains the drug of choice for analgesia in severe pain. Meperidine is no longer recommended because of the buildup of a metabolite, normeperidine, which can cause central nervous system excitation and seizures, even for patients with normal renal function. Buprenorphine is a mixed narcotic agonist and antagonist that has a longer duration of action than morphine. To be effective, systemic opioids must be given in adequate dosage in the immediate postoperative period. Consideration should be given to IV administration, which is more reliable than IM or oral administration. The principal side effect in the postanesthetic period is respiratory depression, and it may be particularly pronounced in elderly patients. Respiratory depression can be treated with 0.4 mg of naloxone given intravenously. In a mixed agonist–antagonist like buprenorphine, naloxone may have less effect, and 2 mg/kg of doxapram, a respiratory stimulant, given intravenously is preferable. Opioids may cause vasodilatation and secondary hypotension, which can initially be treated with elevation of the feet.

An essential part of postoperative pain control is use of nonnarcotic medications on a regular dosing scale to provide a baseline level of pain relief. Current American College of Surgeons guidelines recommend that acetaminophen be given as a component of multimodal pain relief (69). Acetaminophen is present in many oral medications used when the patient is capable of oral intake (e.g., acetaminophen with oxycodone or codeine).

The total dose of acetaminophen should not exceed 4 g daily, to lessen the chance of liver toxicity. NSAIDs and selective COX-2 inhibitors can also play an important adjunctive role in postoperative pain relief. The combination of NSAIDs and opioid potentiates analgesia. NSAIDs are anti-inflammatory, antipyretic, and decrease platelet adhesion. The side effects of gastrointestinal bleeding or renal toxicity are low, but are a concern. In most otolaryngology operations, the routine use of NSAIDs should be considered as soon as the risk of bleeding at the operative site is minimal. COX-2 inhibitors do not cause platelet dysfunction, but there is concern about cardiovascular complications in long-term use, and they are not used in patients undergoing cardiac bypass.

The injection of a long-lasting local anesthetic, such as bupivacaine, into the incision can help reduce immediate postoperative pain. This can help improve early mobilization, especially important in the outpatient surgical setting common to many otolaryngology procedures. Other adjunctive procedures, such as transcutaneous electrical nerve stimulation, cryoanalgesia, and epidural-intrathecal opioid administration, are treatment modalities used in other specialties but less frequently in head-and-neck surgery. In patients with difficult or refractory pain management, consultation with a pain service is beneficial.

SURGERY IN THE CHEMICALLY DEPENDENT OR ALCOHOLIC PATIENT

The most common substances of abuse exhibiting a withdrawal syndrome are depressants, stimulants, and opioids (70). Even therapeutic medications, such as aspirin, anticoagulants, and beta blockers, can also have a withdrawal syndrome characterized by the opposite effect of the drugs. For example, rapid or overcorrection of anticoagulation can lead to a hypercoagulable state. No purposeful attempt to "withdraw" the substance abuse patient should be made during the perioperative period. Instead, the medical treatment should be designed to support the addicted patient. Stimulant withdrawal, such as from cocaine, is managed with dopaminergic agents such as amantadine, or antidepressant drugs such as desipramine, with lorazepam, 2 mg, used for more acute agitation. Perioperative treatment of depressant drug withdrawal (other than alcohol) to medicines such as the benzodiazepines or barbiturates usually involves reinstituting the abused medicine at a lower dose, and gradually weaning off over 5 to 6 weeks. In opioid abuse, narcotic analgesics should be used for pain control in the immediate postoperative period. Thereafter, support can be maintained by a number of different withdrawal schemes. Clonidine, 0.1 mg, orally every 4 hours, initially, for the first 36 hours, followed by gradual weaning, helps minimize the opiate abstinence syndrome (70). As an alternative, methadone 10 to 30 mg, orally is given initially with subsequent doses every 8 to 12 hours, depending on symptoms. Naloxone, 0.4 mg, i. v., should be available to reverse narcotic overdosage.

The alcoholic has several specific abnormalities that should be addressed. After only a few hours without alcohol, the patient may begin to show signs of mild withdrawal, including irritability, tremulousness, and nausea. In addition to reassurance, chlordiazepoxide, 25 to 100 mg, orally every 6 hours, may help prevent the onset of more severe delirium tremens, which usually starts 48 to 72 hours after alcohol cessation and lasts 3 to 5 days (70,71). Delirium tremens is an unwanted complication in the otolaryngology patient, especially for patients who have undergone a major head-and-neck resection, tracheostomy, and flap reconstruction. Delirium tremens develops in 5% to 10% of patients with alcohol withdrawal, characterized by increased irritability, agitation, hallucinations, fever, tachycardia, and disorientation, and can have mortality up to 15%. Seizure activity may be present but usually of short duration and not requiring antiepileptic medications. Medical treatment includes increasing chlordiazepoxide to 100 mg, IV or PO, every 2 to 6 hours, up to 500 mg in the first 24 hours, and tapering thereafter, depending on symptoms. In older patients, shorter-acting lorazepam, 1 to 2 mg IV or PO, every 6 to 8 hours, can be used, and oxazepam, which is excreted by the kidneys, can be used in patients with hepatic failure, at a dose of 15 to 30 mg, PO, every 6 to 8 hours.

The alcoholic also has medical problems pertinent in the surgical patient. Hemostasis in the alcoholic patient can be altered significantly. The patient may have prominent bleeding problems secondary to insufficient or abnormal platelets found in alcoholism, in addition to decreased coagulation factors if alcoholic liver disease is present. All alcoholic patients should have thiamine, 100 mg, and folic acid, 1 mg, IV, followed by oral thiamine, 100 mg, daily with a multiple vitamin containing folic acid and vitamin B_{12}. Metabolic problems also are important in alcoholic patients, who are especially susceptible to hypoglycemia because of depleted glycogen stores. For this reason, all preoperative alcoholic patients should have intravenous fluids with glucose and a minimal fasting period before surgery. Phosphate, magnesium, and potassium are frequently low and should be measured and replaced as necessary.

HIGHLIGHTS

- Routine preoperative laboratory evaluation is not productive in healthy patients, has minimal predictive value for postoperative complications, and should evaluate known medical conditions.
- Correction of hemostatic disorders requires the replacement of specific clotting factors, FFP, or platelets rather than the use of whole blood.

- Prevention is the best form of therapy for DVT, and it involves mechanical methods and consideration of low-dose anticoagulant therapy.
- In the diabetic, adequate carbohydrates are provided during and after surgery to prevent protein catabolism and lipolysis. Serum glucose is controlled by monitoring blood glucose and giving supplemental regular insulin as needed. A sliding scale for insulin dosing is not routinely used.
- Thyrotoxic storm is treated with medications to block production or release of thyroxine (e.g., PTU, iodides), control cardiac symptoms (e.g., propranolol if tachycardia, diuretics and digitalis if heart failure), and replace other deficiencies (e.g., hydrocortisone).
- A search for the underlying cause for postoperative hypotension or hypertension should be sought rather than instituting treatment only with pharmacologic agents.
- Pulmonary problems are the most common postoperative complication, and deep breathing, clearance of secretions, and frequent turning are begun immediately after surgery.
- Stress ulceration is the most common cause of postoperative gastrointestinal bleeding. Reduction in gastric acidity by histamine blockers, PPIs, and early enteral feedings are the most effective prophylactic measures.
- The most important intraoperative consideration in chronic renal failure is to maximize renal perfusion and minimize further kidney damage.
- The primary goals in treating postoperative seizures are to stop the seizure, avoid hypoxia, and avoid injury to the operative site. Benzodiazepines, phenytoin, and phenobarbital are pharmacologic agents of choice.
- Noninfectious causes of postoperative fever are common, especially in the immediate postoperative period.

Operative Technologies

4

Paul G. van der Sloot *Runhua Hou*

INTRODUCTION

The nature of surgery is such that operative technologies provide impetus for change and progress with improved operative outcomes. Operative technologies are numerous and diverse, maybe more so in otolaryngology than any other surgical specialty. This chapter represents an overview of operative technologies in otolaryngology. It is by no means comprehensive. An array of technologies are presented that include new technologies that have come into widespread practice, developing technologies that are at the cusp of general use and old technologies for which new applications have been recently developed.

DISSECTION/HEMOSTASIS TECHNOLOGIES

A number of recent tools have been developed that provide the ability to dissect and achieve hemostasis virtually simultaneously. These instruments tend to be most useful in operative cases where space is limited and a clean operating field is particularly important. These include cases like parotidectomy, thyroidectomy, parathyroidectomy, tonsillectomy, and microvascular free flap harvest.

Tonsillectomy

In the case of tonsillectomy, technologies have been adopted that attempt to minimize pain associated with conventional cautery without increasing the risk of post-tonsillectomy bleeding. Coblation involves the dissociation of isotonic saline into sodium ions between the electrodes of the coblator, which breaks molecular bonds between cells. The temperatures generated by the coblator are between 45°C and 85°C as compared to 400°C and 600°C with electrocautery. This, along with the fact that coblation tonsillectomy is usually performed using an intracapsular technique, has been shown to decrease the duration of postoperative pain and speed the return to a normal diet (1). The disposable coblator components do create an added cost for the procedure. Coblation has also been used for a variety of nasal surgeries like turbinate reduction, hemostatic debulking of tumors to allow endoscopic visualization, and the removal of encephaloceles.

Other techniques that have been used successfully include argon plasma scalpels where argon gas is ionized by an electrode creating a beam of argon plasma through which current flows allowing for tissue dissection using molecular resonance technology where alternate current high-frequency electron waves at well-defined and varying wavelengths create electron energy quanta, which, when in resonance with cell molecular bonds, causes them to break (2,3). The main thrust of these technologies is to decrease pain without increasing the risk of hemorrhage in the postoperative period.

Thyroidectomy and Parotidectomy

Ultrasonic shears (or the harmonic scalpel) involve the use of ultrasonic blade vibrations at 55,000 Hz that denature proteins and create a coagulum that seals vessels. Vessels of up to 2-mm diameter can be sealed using this technique. Because no electrical energy is transferred to the patient, it may be ideally suited for areas of dissection near nerves. Some studies have suggested decreased blood loss and decreased frequency of facial nerve injury are seen with the use of ultrasonic shears for superficial parotidectomy (4). Similar results have been obtained for thyroidectomy. Despite the common use of this instrument for these procedures, basic science researchers have shown that activation of the shears near the nerve, particularly closer than 2 mm or when it is activated in the vicinity for greater than or equal to 3 seconds, does result in a change in peak latency for the recurrent laryngeal nerve in a rabbit model (5).

Microvascular Free Tissue Harvest

Several donor sites for free tissue harvest involve the harvest or division of large muscle bellies. The fibular osteocutaneous free flap and the anterolateral thigh myofasciocutaneous flap with or without significant vastus lateralis muscle are commonly used donor sites that require substantial muscle division. Vascular perforators in the muscle at irregular intervals make the muscle division tedious, and conventional harvest can be prolonged with blood loss hampering field visualization. Increasingly, ultrasonic shears are used to limit time required to harvest, decrease blood loss, and improve field visualization.

TECHNOLOGIES TO IMPROVE VISUALIZATION OF THE OPERATIVE FIELD

Sinus Surgery

Endoscopes with variably angled lenses have been in conventional use for sinus surgery for many years. They have paved the way for less morbid surgery by allowing the sinus surgeon to visualize the tissues more precisely. The surgeon is thus able to limit trauma to those areas of the nose and sinuses that have no bearing on the desired outcome of surgery. In this way, it has decreased the morbidity of sinus surgery while improving outcomes.

Skull Base Surgery

The combination of improved endoscopes and cameras coupled with image-guided navigation and even real-time imaging has expanded the bounds of endoscopic skull base surgery (6). Although the basic instruments are similar to sinus surgery instruments, more varied angles for cutting and grasping instruments, extended guards for drills, and other modifications like endoscopic bipolar cautery have all contributed to the advancement of endoscopic skull base surgery. Self-irrigating endoscope technology has also allowed for more efficient surgery by limiting the need for scope removal and cleaning during the procedure. Although robotic surgery has not become a standard for skull base surgery at this point, increasing miniaturization of instruments and cameras as well as work on multiply articulated instruments may make robot-assisted surgery of the skull base a standard in the future (7).

Thyroid and Parathyroid Surgery

Minimally invasive procedures of the thyroid and parathyroid glands have evolved as a result of a desire for improved cosmesis, particularly in certain cultural groups, and a desire to limit pain and hospital stay. Video-assisted thyroidectomy involves a reduced central neck incision, subsequent blunt dissection to divide the muscular raphe in the midline, blunt dissection over the capsule of the thyroid, and subsequently the use of a 5-mm 30-degree laparoscope combined with the harmonic scalpel to take down the superior pole vessels and subsequently identify the recurrent laryngeal nerve. The remainder of the lobe is then separated from the parathyroids, Berry's ligament is divided, and the lobe is dissected off the trachea. Nodules greater than 3 cm and a history of thyroiditis may limit this technique, but with appropriately selected patients, complication rates that are comparable to conventional surgery are quoted in the literature (8,9).

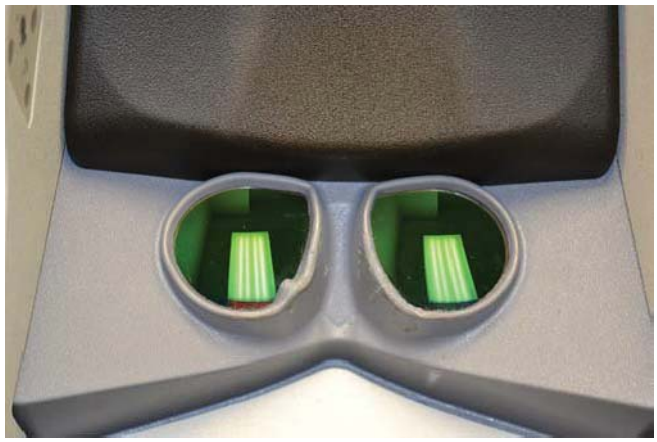

Figure 4.1 Robot stereo viewer.

An extension of the desire to limit any visible scar is the transaxillary thyroidectomy, often done with robotic assistance. The da Vinci Surgical System (Intuitive Surgical, Sunnyvale, CA) provides binocular (Fig. 4.1), three-dimensional (3D) magnification, tremor filtration, and greater degrees of freedom in the mobility of instruments. The surgeon, after preparing the surgical field, sits in a console with 3D visualization of the field and ergonomic hand and foot controls. Scaling of movement up to 5 to 1 can be set, and any tremor is filtered as the surgeon's movements in the console are transferred in real time to the instruments in the patients (Fig. 4.2). Clutching of the wrist

Figure 4.2 Robot master hand controller.

rotational movements allows for 360 degrees of rotation for a given instrument. In the case of transaxillary thyroidectomy, the patient station is docked on the contralateral side. The 30-degree endoscope is used facing downward through 5- to 6-cm vertical incision in the ipsilateral axilla. Dissection is in a subcutaneous plane until the sternocleidomastoid muscle is identified. It is subsequently carried down between the two heads of the muscle. Indications for this approach include small nodules less than 2 cm including well-differentiated malignancies without extracapsular spread. High BMI may be a contraindication to this approach (10).

Transoral Robotic Surgery

Historically, tumors of the oropharynx, particularly those of the base of tongue, required extended access procedures to be able to visualize and remove tumors at these locations. Often, a lip and mandibular split procedure was required. Subsequent patient function and cosmesis was at the very least temporarily impaired. This was one of the driving forces behind the move toward organ-preserving therapy. Robotic surgery has been used as a minimally invasive approach for urologic surgery for some time. More recently, this technology has been applied to tumors of the oropharynx to provide a surgical alternative to nonsurgical organ-preserving therapies. Transoral robotic surgery (TORS) has been successfully used for tumors of the oropharynx in particular. The potential benefits of the technology are listed above.

Patient selection is critical for these cases. Mouth opening must be adequate and paralysis intraoperatively is usually required. Usually, a Feyh-Kastenbauer or Dingman retractor is used to keep the mouth open. A second assistant at the head of the bed is also required for additional retraction and occasional help with hemostasis. Thirty-degree binocular endoscopes are usually used for the tongue base. Zero-degree endoscopes are often used for the tonsillar fossa (Fig. 4.3). Recent studies have shown that even when combined with adjuvant therapy, functional outcomes 12 months posttreatment including swallowing, speech, and diet are not significantly different from pre-op assessments (11). Human papillomavirus–related oropharyngeal malignancy, with its increasing incidence and brighter prognosis, has prompted work on deintensification of therapy. TORS appears to have a role to play in maintaining oncologic outcomes while minimizing long-term morbidity.

Figure 4.3 Basic setup for the robot with central camera arm and lateral instrument arms.

VIDEO (ROBOTIC RESECTION ORO/HYPOPHARYNGEAL LESION)

Oncologic Tools

Photodynamic Therapy

The basic idea behind photodynamic therapy is administration of a photosensitizing drug followed by the application of light causing a photochemical reaction that results in tissue damage. Intraoperatively, needles are placed in a tumor and optical fibers are threaded through these needles. Guidance for needle placement can include endoscopy, ultrasound, and CT and MRI technologies. Temoporfin is a commonly used photosensitizing agent that is typically given IV 90 minutes prior to light therapy. A 652-nm diode laser is then used at 20 J per location. This technique has been shown to decrease tumor bulk and improve functional status in unresectable and recurrent tumors (12). Photodynamic therapy shows particular promise for dysplasia and carcinoma in situ.

High-Resolution Microendoscopy and Confocal Microscopy

High-resolution microendoscopy is showing promise as an adjunctive measure for evaluation of margins in head and neck epithelial malignancies. The technology involves direct contact between a high-resolution endoscope and an epithelial surface. Prior to contact, the epithelium is painted with a contrast agent like proflavin. Excitation light is delivered through the fiberoptic bundle. Fluorescence emission from the epithelial surface is then captured by a charge-sensitive camera, and digital images are obtained. Differences in the obtained images allow for differentiation of normal mucosa from dysplasia and carcinoma with good histologic correlation (13). Laser scanning microscopy (confocal microscopy) with endoscopes has been combined with the utilization of laser light to produce topographical images of the epithelium. When combined with rigid endoscopes, evaluation of tissue just below the surface epithelium can also be obtained. Differentiation between normal, dysplastic, and cancerous epithelium shows good correlation with histologic analysis (14).

Lasers

Lasers have been utilized in a number of ways in the field of otolaryngology. We focus on relatively recent developments that have had an impact on the practice of otolaryngology

Angiolytic Lasers

Photoangiolysis involves the ablation of small superficial blood vessels by targeting hemoglobin. The potassium titanyl phosphate (KTP) laser has a wavelength of 532 nm, which correlates closely with the peak absorbance of hemoglobin. By ablating the supporting microcirculation of a lesion, whether it is benign or even malignant, the growth of the lesion is terminated. Delivery through flexible fibers permits use with rigid or flexible endoscopes. This makes ideal for in-office procedures.

This technology has been particularly useful in the treatment of a variety of laryngeal lesions including vascular ectasias, papilloma, polyps, and granulomas. It shows promise in the treatment of dysplasia and early glottic cancers as well (15).

CO_2 Laser (Flexible Fiber Delivery)

Through the combination of CO_2 laser energy and near-perfect mirrors, a flexible delivery system has been designed that allows for broader application of the CO_2 laser (Omniguide, Cambridge, MA). A hollow core delivering a cooling flow of inert gas allows for a cleaner field, improved coagulation, and cooling of the treated tissues, limiting thermal injury. Of course, it can be delivered with a flexible scope but also with a variety of hand pieces. This technology is used in variety of otolaryngologic procedures from stapedectomy and cholesteatoma removal to laryngeal papilloma and cancer removal. It also has proved very useful in tracheal surgery to debulk tumors and to make radial cuts for tracheal stenosis. Furthermore, work is currently being done on coupling the flexible CO_2 laser with robotic technology.

Image-Guided Navigation

Image guidance has now been used since the early 1980s and has become routinely used in revision sinus surgery and complex endoscopic skull base surgery. There are several platforms available. In general, a preoperative CT scan is performed and images are referenced to fixed points placed close to the surgical site. This provides for an increased margin of safety relative critical structures at risk during these procedures. In general, these systems do not provide real-time evaluation of the patient's anatomy. However, compact, portable CT scanners are available that can couple real-time CT images with existing image guidance systems to give up-to-date information as surgery modifies existing anatomy (16).

Topical Hemostatic Agents

Topical hemostatic agents are commonly used in otolaryngology. In general, they can be divided into four categories: fibrin sealants, gelatin-based products, oxidized cellulose, and collagen products. Fibrin sealants are now commonly used in otolaryngologic surgeries. Tisseel (Baxter) is the most commonly used product. It comes in two vials. The first vial is composed of human fibrinogen and bovine aprotinin, an inhibitor of proteases including plasmin. The second vial contains human thrombin and calcium chloride. The two vials are combined to form a solid fibring sealant. Crosseal (Ethicon) is a more recently developed product and contains human fibrinogen and thrombin but no bovine aprotinin. These products have been successfully used in the context of parotidectomy and rhytidectomy to reduce the potential for hematoma and ecchymosis (17).

Gelatin-based products have hemostatic properties that are not linked to the clotting cascade and are thought to be physical rather in chemical in nature. Gelfoam (Baxter) is made of purified pork skin gelatin and typically is used in sponge form, often combined with purified thrombin. An important property of gelatin sponge is its ability to absorb up 40 times its weight in fluid and expand its volume up to 200%. Depending on the application, this may be a positive or negative attribute. Floseal (Baxter) combines human thrombin with bovine gelatin matrix granules. These are mixed at the time of application. Volume expansion is minimal, and because it comes in liquid form, it is easy to apply in limited access procedures. Surgiflo (Ethicon) has a similar constitution and utilization.

Oxidized cellulose, like Surgicel (Ethicon), has long been used as a topical hemostatic agent. It is produced as a knitted fabric from regenerated plant-derived cellulose, which is oxidized. It acts as a scaffold for clot formation. Surgicel comes in a number of different forms, from a thick woven product to lightweight tufted layers depending on the nature of the application. Besides its hemostatic properties, it has bacteriocidal properties. Surgicel is used extensively as a topical hemostatic agent for epistaxis and with intranasal surgical procedures.

Microfibrillar collagen products like Avitene (Davol, Inc.) are made by purifying bovine collagen and processing it into microcrystals. Collagen products induce the intrinsic pathway of the coagulation cascade. They have been in use since the 1970s. Developments have been made recently in the format of these products. They are now available in powder, woven–knit, and sponge form. In some randomized control trials, microfibrillar collagen has been shown to be a superior topical hemostatic agent than oxidized cellulose (18).

Wound Adhesive/Hemostatic Agents

Cyanoacrylate adhesives were developed in the 1940s by Kodak. As early as 1965, they were used for tympanic

membrane repair. Liquid cyanoacrylate monomers polymerize to form long chains in the presence of hydroxyl ions. Water from human tissues activates the polymerization reaction and the "glue" rapidly sets. Although it is mainly used for closure of small skin incisions, it has been used for corneal perforations, varices, and other vascular repairs, as well as skin grafting. Besides their adhesive properties, cyanoacrylate adhesives also have good antimicrobial properties.

Tissue Substitutes

Dural Substitutes

Repair of dural defects, although usually performed with autologous tissues, is sometimes performed with engineered tissues. In most cases, this is performed using collagen-based dural substitutes. Duragen (Integra, Life Sciences) is cross-linked collage foam produced from bovine Achilles tendon. Duraguard (Synovis) is a cross-linked collagen product produced from bovine pericardium. Durarepair (Integra, Life Sciences) is a non–cross-linked bovine collagen implant derived from bovine fetal dermis. Durarepair and Duraguard are stronger materials that are usually sutured in place. Duragen is more fragile, and although it can be sutured in place, it is usually used as an onlay graft. Duragen is typically absorbed by 1 month, while both Durarepair and Duraguard are still identifiable but integrated by 6 months implantation. Duragen is quickly penetrated by native cells, whereas Durarepair and Duraguard take much longer to integrate. In short, the physical properties of Duraguard and Durarepair are useful where a long-term dural substitute is required. Duragen is more useful for the repair of small defects, not requiring the mechanical strength of native dura (19).

Skin Substitutes

The definition of "skin substitutes" varies widely. We define them as materials containing normally occurring skin elements that are incorporated into native skin. Skin substitutes can be categorized into the skin layers being replaced. Epidermal replacements contain keratinocytes. Allogenic keratinocytes can be harvested from fresh human donor skin, neonatal foreskin, and occasionally other harvested skin. One to two months following placement, autologous keratinocytes have replaced the allogenic cells. The use of these epidermal substitutes is relatively limited. More commonly, dermal skin substitutes are used for skin replacement. These can be divided into acellular and cellular substitutes, the latter usually containing fibroblasts and endothelial cells. Alloderm (Life Cell Corporation) is a commonly used acellular dermal replacement containing collagen and elastin derived from human donor skin. Apligraf (Organogenesis) is an example of a cellular product containing collagen, glycosaminoglycans, allogenic keratinocytes, and allogenic fibroblasts derived from bovine tendon and neonatal foreskin. Whether acellular or cellular, these materials provide a scaffold for the invasion of fibroblasts. These fibroblasts produce extracellular matrix and cytokines, which eventually lead to the replacement of the skin substitute. This substitution can take place over weeks, months, or years depending on the material (20).

HIGHLIGHTS

- Temperatures generated by the coblator are about 1/10 those of electrocautery when used for tonsillectomy.
- Ultrasonic shears denature proteins, creating a coagulum that seals vessels.
- Video-assisted thyroidectomy may be limited to nodules less than 3 cm in greatest dimension.
- Robotic surgery benefits from binocular magnification, 360 degrees of wristed motion, and scaled movements with tremor suppression.
- TORS in selected oropharyngeal cancer patients reduces functional morbidity by avoiding lip-splitting, mandible-splitting surgery and by reducing the dose of radiation or even eliminating it entirely.
- Photodynamic therapy using light-sensitizing agents and light can reduce bulk in unresectable tumors and shows promise in the treatment of dysplasia and carcinoma in situ.
- Confocal and high-resolution microendoscopy show promise in identifying dysplasia and cancer on epithelial surfaces.
- Photoangiolysis with the KTP laser can be used to ablate the supporting microcirculation of an array of laryngeal lesions by utilizing a wavelength that closely corresponds to the peak absorbance of hemoglobin.
- Topical hemostatic agents can be divided into fibrin sealants, gelatin-based products, oxidized cellulose preparations, and microfibrillar collagen products.
- Dermal skin substitutes can be divided into cellular and acellular products. In both cases, the material provides a matrix for invasion by native fibroblasts that induce further incorporation into the surrounding skin.

Critical Care

5

Jon D. Simmons *Kimberly A. Donnellan*

The field of critical care medicine is complex and rapidly changing. The goal of this chapter is to familiarize the otolaryngologist with some of the basic principles of critical care medicine and provide evidence for common postoperative complications often seen in the intensive care unit (ICU). This chapter increases a general understanding of critical care medicine while facilitating a good working relationship with the intensivist.

TISSUE OXYGENATION AND ORGAN PERFUSION

Many physicians struggle with understanding the difference between tissue oxygenation and organ perfusion. Although these topics are often regarded as synonymous, they are not. This misunderstanding is likely the reason for inappropriate fluid resuscitation and blood transfusions, and emphasizes the importance of understanding their differences and treatment.

OXYGEN DELIVERY

In general terms, oxygen delivery (DO_2) refers to the amount of oxygen that is delivered to the tissue. It does not refer to the amount of oxygen uptake at the cellular level. The lack of oxygen delivered into the tissues can be due to several defects including: respiratory failure, inadequate delivery to the tissues, and defective uptake into the tissue. DO_2 to the peripheral tissues can be calculated by using the following formula.

$$DO_2 = CO \times 1.34 \times Hb \times SaO_2 + (PaO_2 \times 0.003)$$

where CO, cardiac output; Hb, hemoglobin; SaO_2, oxygen saturation; and 1.34 is a conversion factor that relates how much oxygen can bind to hemoglobin. (PaO_2 × 0.003) describes the amount of oxygen that is dissolved in blood and not bound to hemoglobin.

Notice the amount of oxygen delivered to the peripheral tissues as dissolved oxygen that is not attached to hemoglobin is miniscule (PaO_2 × 0.003). Therefore, when the oxygen saturation of hemoglobin is high, it does not help to provide excess supplemental oxygen. The CO, Hb, and SaO_2 all have equal contributions to the amount of oxygen delivered to the peripheral tissue. Therefore, CO and Hb are as important as the oxygen content in the blood.

OXYGEN EXTRACTION

Oxygen extraction (VO_2) refers to the amount of oxygen that is extracted from the blood into the peripheral tissues at the capillary level and utilized by the cell. Since oxygen is not stored in the cell, extraction (consumption) is equal to the amount of oxygen utilized by the cell. The rate of oxygen extraction is expressed by the following formula:

$$O_2 = CO \times 1.34 \times Hb \times (SaO_2 - SvO_2)$$

where CO, cardiac output; Hb, hemoglobin; SaO_2, arterial oxygen saturation; SvO_2, venous oxygen saturation; and 1.34 is a conversion factor that relates how much oxygen can bind to Hb.

The most important concept to understand in tissue oxygenation is that delivery (DO_2) and extraction (VO_2) are not the same. The rate of oxygen extraction from the blood into the peripheral tissues (VO_2) is done at a constant rate. In normal circumstances (a normal DO_2), only 25% of the oxygen in the blood is extracted into the tissues. Therefore, 75% of the oxygen in the blood is not extracted into the tissue and is considered "extra." The amount of oxygen extracted into the tissue is better described as the oxygen extraction ratio (O_2ER).

$$O_2ER = VO_2 / DO_2$$

The O_2ER reveals that as the delivery of oxygen to the tissue (DO_2) decreases, the amount of oxygen extracted into the cell is the same (no change in VO_2). However, the O_2ER will increase (more oxygen disassociation from Hb) to provide the constant transfer of oxygen into the cell.

At some point, the delivery of oxygen (DO_2) will be low enough not to provide the constant flow of oxygen into the cell, which is needed for aerobic metabolism. This is the point that must be identified by the physician. This level is often referred to as the critical DO_2. This is the level that cellular metabolism changes from aerobic to anaerobic metabolism. Therefore, increasing the delivery of oxygen without a level below the critical DO_2 is often unnecessary and may carry the risk associated with the treatment (i.e., inappropriate blood transfusions).

Since the DO_2 is irrelevant until it reaches the critical DO_2 signifying a drop in tissue oxygenation (VO_2), the decrease in VO_2 is the important factor. The measurement of the oxygen consumption (VO_2) requires invasive devices, like a Swan-Ganz catheter or Metabolic cart, that are not readily available in all situations. However, the O_2ER is closely linked to the oxygen consumption (VO_2) and can be easily measured since most critically ill patients have a central venous catheter. We know from many human and animal studies that the oxygen consumption (VO_2) starts to drop with an O_2ER of approximately 50%. The O_2ER can be calculated by subtracting the amount of oxygen in the venous blood from the oxygen in the arterial blood. Since the peripheral tissues do not store oxygen, this difference of oxygen content between the arterial and venous blood is the amount of oxygen extracted at the cellular level. This can be expressed as:

$$O_2ER = SaO_2 - SvO_2$$

where SaO_2, arterial oxygen saturation; SvO_2, venous oxygen saturation.

The SaO_2 is easily measured with noninvasive devices such as a pulse oximeter. The SvO_2 is most accurate when obtained in the pulmonary artery that is distal to where the coronary sinus empties desaturated venous blood into the right atrium from the myocardium. A Swan-Ganz catheter is needed to obtain this "mixed venous" (SvO_2) measurement in the pulmonary artery. However, the venous oxygen saturation taken from the superior vena cava ($ScvO_2$) from the tip of a "central line" is in close proximity to the pulmonary artery oxygen saturation (SvO_2). The average variation between these measurements is about 5% (1). So the oxygen saturation from a central venous catheter ($ScVO_2$) can fairly accurately replace the mixed venous saturation (SVO_2), especially when following trends. This allows the physician to fairly accurately predict the oxygen consumption without a Swan-Ganz catheter.

ANAEROBIC METABOLISM

As stated previously, the switch from aerobic to anaerobic metabolism occurs at the point where the supply of oxygen (DO_2) cannot meet the metabolic demands (VO_2) at the cellular level. This occurs at an O_2ER below approximately 50%. Another indirect marker of anaerobic metabolism is lactate. The serum lactate level can be an effective marker of cellular oxygenation but using this to solely determine end-organ perfusion can be problematic. Since lactate is cleared by the liver, its clearance is variable and therefore is not the best immediate marker to guide therapy.

BLOOD TRANSFUSIONS IN THE ICU

Blood transfusions are often a lifesaving therapy in surgical ICUs. However, blood transfusions are also one of the most misused resources available to physicians. We will describe the indications, side effects, and evidence surrounding the use and misuse of blood transfusions in the ICU.

The effect that packed red blood cells (PRBCs) have on tissue oxygenation is often misunderstood. As described earlier, the delivery of oxygen to the tissues is dependent upon cardiac output, amount of hemoglobin, and the oxygen saturation. In normal individuals, only 25% of delivered oxygen (DO_2) to the peripheral tissue is utilized (VO_2). Therefore, an excess of oxygen is delivered to the tissue. As the DO_2 decreases (i.e., decrease in hemoglobin), the amount of oxygen extracted from hemoglobin increases, but the oxygen uptake into the tissues (VO_2) remains unchanged. So, giving a blood transfusion when the extraction ratio is above 50% will not increase the amount of oxygen utilized by the cell. In fact, giving a blood transfusion in the setting of isovolemic anemia will often decrease the VO_2 due to the increased viscosity of PRBCs causing a decrease in perfusion of the microcirculation.

Blood transfusions are analogous to a "Blood Transplantation" and the side effects of blood transfusions are similar to most other transplanted organs from another human (allograft). The previous concerns for the infectious risk of hepatitis and human immunodeficiency virus are now very uncommon (2). The most notable side effects consist of immunosuppression and rejection. The immunomodulating effects of receiving a blood transfusion increase the risk of the recipient to developing nosocomial infections, acute respiratory distress syndrome (ARDS), and possible development of autoimmune diseases later in life (3,4). However, the most important immunomodulating effect of blood transfusions in postoperative oncologic patients is the significant increase in cancer recurrence and death (5–7). Most of the evidence regarding cancer recurrence is in colorectal cancer but some studies have specifically examined the recurrence rate after squamous cell carcinoma (SCC) of the head and neck (8,9). Jones et al. (6) examined the recurrence/metastasis rate in Stage 3 SCC in the head and neck in regards to blood transfusions. They found the recurrence/metastasis rate of SCC to be significantly higher in the group that received a blood transfusion (64% vs. 22%). This reason alone should prompt careful consideration prior to giving a blood transfusion in postoperative patients.

More recently it has been shown that not all units of PRBCs are equal (9) and that the length of storage makes a significant difference in the quality of PRBCs that are transfused. Longer storage times are associated with ATP depletion, decreased 2,3 DPG, protein oxidation, and loss of membrane flexibility. The combination of the membrane flexibility and decreased 2,3 DPG would conceptually reduce the quality of the PRBC transfusion the most. The loss of membrane flexibility limits the ability of the red blood cell (RBC) to pass through the microvascular circulation, and the decrease in 2,3 DPG will cause a left shift in the oxygen–hemoglobin disassociation curve causing less off-loading of oxygen to the peripheral tissues. The loss of membrane flexibility and increased viscosity of PRBCs are often cited as being the culprits for decreasing the DO_2 following the administration of PRBC. This is best displayed in a study examining the progressive normovolemic hemodilution in canine skin flaps (10). The authors progressively infused a colloid solution while removing blood from the canine to drop the hemoglobin while maintaining adequate intravascular volume and cardiac output, which effectively decreased the viscosity of the blood (normovolemic hemodilution). As the hemoglobin dropped, the authors measured the tissue oxygenation on the skin flaps. They found that as the hemoglobin decreased, the tissue oxygenation actually improved instead of the decline. The tissue oxygenation of the normal skin continued to improve until the canine reached a hemoglobin of 4.

In 1942, Adam and Lundy (11) suggested a hemoglobin level of less than 10 should prompt a blood transfusion. Since that time, study after study has attempted to find the optimal hemoglobin level that would necessitate a blood transfusion in the nonhypovolemic patient. Thus far, the Transfusion Requirement in Critical Care (TRICC) trial is the only prospective randomized controlled trial with an adequate sample size to examine this issue. The TRICC trial (12) examined the difference between a hemoglobin transfusion trigger of 7 versus 10 in euvolemic patients in the ICU. The authors concluded "A restrictive strategy of red-cell transfusion is at least as effective as and possibly superior to a liberal transfusion strategy in critically ill patients, with the possible exception of patients with acute myocardial infarction and unstable angina." This was later confirmed in another prospective randomized controlled trial (13). In 2006, Marik et al. (14) performed a systematic review of the literature and concluded "the need for a PRBC transfusion should be individualized based on a patient's clinical circumstances rather than an arbitrary hemoglobin concentration."

SHOCK

The term shock is used very commonly throughout the medical field but is often poorly understood. In simple terms, shock is synonymous with tissue dysoxia. The treatment of shock is guided by correcting the variables in the DO_2 equation that are abnormal (CO < 6 L/min, Hb < 7, and oxygen saturation < 90%). There are two situations in which shock is not caused by decreased DO_2: mitochondrial dysfunction (sepsis, cyanide, etc.), and vasodilatory states (systemic inflammatory response syndrome, sepsis, spinal shock, etc.). There is no treatment for the mitochondrial dysfunction seen in sepsis other than supportive care. Vasopressors are likely the optimal treatment for vasodilatory states (i.e., systemic inflammatory response syndrome) in the setting of normovolemia.

VASOACTIVE AGENTS IN THE ICU

The use of vasoactive infusions in the ICU is not uncommon and their use can be lifesaving. However, severe complications can be associated with the use of vasopressors. There is not good evidence to support which vasopressor to use in a given situation or if they improve outcomes in shock. However, we will review commonly used vasopressors in the ICU and the ideal situations in which they should be applied (see Tables 5.1 & 5.2).

There are several things in which a physician should consider prior to initiating vasopressor infusion. These considerations should include: cardiac output, volume status, peripheral vascular resistance, and causes of hypotension. All four of these considerations are very important and must be known prior to initiating any vasopressor for hemodynamic support.

Common Pitfalls to Avoid with Vasopressors

Systolic Left Ventricular Failure

In patients with severe systolic dysfunction, a rapid increase in peripheral vascular resistance will cause increased myocardial work and worsening cardiac output with rapid decline. These patients may benefit from inotropic support or decreased peripheral vascular resistance rather than a vasoconstrictor.

Diastolic Dysfunction

Diastolic dysfunction is often misunderstood. A simplistic view of diastolic dysfunction is to imagine a muscular bodybuilder that cannot straighten his arms due to the tight bicep muscle. This bicep muscle is very strong but it cannot completely relax. This is analogous to a hypertrophied left ventricle in diastolic dysfunction. The left ventricle is unable to stretch and accept enough preload to generate sufficient cardiac output despite being able to contract normally. It is a preload problem; therefore, the ejection fraction is normal despite a low cardiac output. Although ventricular hypertrophy is the most common type of diastolic dysfunction, any disease process that limits the ability of the ventricle to relax is considered diastolic dysfunction. Patients with severe diastolic

	>10–20 µg/kg/min	↑↑↑	↑↑	↔	↑	↑
Norepinephrine	0.01–1 µg/kg/min	↑	↑↑	↑	↔/↑	↑↑↑
Epinephrine	0.01–1 µg/kg/min	↑↑	↑↑	↑	↑↑	↑↑
Phenylephrine	0.5–1 µg/kg/min	↔/↓	↑	↑	↔/↓	↑↑
Vasopressin	0.01–0.04 units/min	↔/↓	↑↑	↑	↔	↑↑
Dobutamine	2–20 µg/kg/min	↑↑	↓/↑	↓	↑	↔/↓

[a]Hemodynamic effects may vary among patients.
[b]The maximum dose should be based on individual institutional policies.
HR, heart rate; MAP, mean arterial pressure; PAOP, pulmonary artery occlusion pressure; CI, cardiac index; SVR, system vascular resistance.

dysfunction can be very difficult to manage perioperatively. If the patient is underresuscitated and placed on a vasoconstrictor in the setting of severe diastolic dysfunction, the cardiac output will quickly decrease as the vasopressor infusion is quickly titrated upward to maintain hemodynamic stability. This type of patient must get adequate volume resuscitation prior to starting a vasopressor for hemodynamic support.

Cardiac Valve Disease

Cardiac valvular disease can be difficult to treat or diagnose without imaging studies (i.e., echocardiogram). Vasopressor therapy can dramatically worsen valvular abnormalities such as but not limited to aortic/mitral stenosis and insufficiency. The immediate clue that a cardiac valve abnormality may be significantly contributing to the hemodynamic instability is a murmur on cardiac auscultation. The presence of a murmur in the setting of hemodynamic instability should prompt an immediate echocardiogram.

Tachycardia

Vasopressors with high beta-adrenergic activity can be highly arrhythmogenic. These medications can create a variety of arrhythmias including: ventricular ectopy, ventricular tachycardia, and sinus tachycardia. Tachycardias that reach rates above 130 often create a decrease in ventricular filling time (decreased preload) that exacerbates the tachycardia. Epinephrine, dobutamine, and dopamine are the usual culprits. Tachyarrhythmias may be indication to decrease the dose or switch to another agent.

Rapidly Increasing Vasopressor Requirements

Any time a vasopressor is initiated and the patient starts to rapidly decompensate or the vasopressor requirement steadily increases, the diagnosis and intravascular volume should be reevaluated immediately. This should always make the physician question the cause of hypotension. Inappropriate use of vasopressors can cause rapid hemodynamic decomposition and can be fatal.

TABLE 5.2 RELATIVE RECEPTOR ACTIVITY OF VASOACTIVE AGENTS

		Relative Receptor Activity				
Agent	**Dose Ranges[a]**	**α**	**β_1**	**β_2**	**Dopamine**	**Vasopressin**
Dopamine	1–3 µg/kg/min	0	+	0	++++	0
	3–10 µg/kg/min	+	++++	++	+++	0
	>10–20 µg/kg/min	+++	+++	+	+	0
Norepinephrine	0.01–1 µg/kg/min	++++	+++	+	0	
Epinephrine	0.01–1 µg/kg/min	+++	+++	++	0	0
Phenylephrine	0.5–1 µg/kg/min	+++	0	0	0	0
Vasopressin	0.01–0.04 units/min	0	0	0	0	+++
Dobutamine	2–20 µg/kg/min	+	++++	+++	0	0

[a]The maximum dose should be based on individual institutional policies.

Types of vasopressors:

Epinephrine: Epinephrine is a naturally occurring catecholamine that has potent β_1 and α_1 properties. The combination and potency of these properties often limit its use in the ICU.

Norepinephrine: Norepinephrine is the most widely used vasopressor in surgical ICUs. It possesses the same α_1 properties as epinephrine but has limited β_1 properties. The reduced β_1 properties limit the associated tachycardia and ectopy that is seen with other β_1 agonists. Norepinephrine is considered the first choice vasopressor in most situations requiring hemodynamic support.

Vasopressin: Vasopressin is identical to antidiuretic hormone, which is secreted by the posterior pituitary. Vasopressin affects V_1 and V_2 receptors as an agonist. The V_1 receptor is found on peripheral blood vessels that causes vasoconstriction. There is some evidence to suggest vasopressin is beneficial as a second vasopressor when the hypotension is refractory to norepinephrine. It should not be used at a dose greater than 0.04 μg/kg due to mesenteric ischemia.

Dobutamine: Dobutamine is a pure other β agonist. Therefore, it has potent inotropic (increased contractility) and chronotropic (increased heart rate) activity. It is often the drug of choice when inotropic activity is needed. However, its potent β_1 activity can create tachycardia and ventricular ectopy at higher doses. The β_2 properties often cause hypotension, which can be counteracted with avoidance of hypovolemia or addition of an α_1 agonist.

Dopamine: Dopamine is still one of the most widely used vasopressors despite the common side effects of tachycardia and ectopy. Due to these side effects, most intensivists use it as an alternative to norepinephrine. Dopamine may be beneficial in early sepsis but is contraindicated in septic shock. The cardiovascular effects and target receptors are dependent upon the dose administered (Tables 5.1 and 5.2). It is important to remember these ranges are approximate and vary in each patient.

Phenylephrine: Phenylephrine is a pure α_1 agonist. It is often used following spinal cord injuries that cause vasodilation. Phenylephrine often causes a reflex bradycardia secondary to the acute vasoconstriction and should be used with caution in patients with bradycardia.

MECHANICAL VENTILATION

The first form of mechanical ventilation was introduced as the "iron lung" in the 1920s. Modern ventilators introduced in the mid-1980s have changed critical care medicine as a specialty. Ventilators are very complex machines with a simple function, to breathe for the patient. Although the concept is simple, the complexity of the interaction between the patient and ventilator can take an entire career to completely understand. Ventilator dysynchrony ("Bucking the Vent") is common and the correct treatment almost never involves sedation. A skilled or experienced intensivist can often immediately determine the etiology of the dysynchrony. The correct treatment for dysynchrony is simple—fix the cause. This involves knowing the intricacies of the ventilator and understanding the different modes available.

Modes of Mechanical Ventilation

Volume Control

Volume control (VC) is a mode of mechanical ventilation commonly used in the medical ICUs. The respiratory rate and tidal volume are set by the physician. When the patient initiates a breath, the ventilator will give the prescribed volume. If the patient does not initiate a breath, the ventilator will give the same prescribed volume. Therefore, the minute ventilation in VC is determined by the respiratory rate multiplied by the prescribed tidal volume (which is not true for synchronized intermittent mechanical ventilation [SIMV]).

Pitfalls with VC

Breath-stacking can be a dangerous complication of VC. This occurs when the patient or ventilator initiates a breath before complete exhalation of the previous tidal volume. By stacking several breaths on top of one another, the mean airway pressures may reach levels high enough to cause barotrauma, pneumothorax, or pulseless electrical activity (PEA). Anytime a patient suddenly develops high airway pressures, PEA, or desaturation; the physician should first disconnect the ventilator from the endotracheal tube to equalize mean airway pressures. This same concept ("air-trapping") often applies to patients with obstructive lung disease who often have prolonged expiratory times.

Synchronized Intermittent Mechanical Ventilation

SIMV is the most frequently used ventilator mode in the surgical ICU. The surgical ICU, unlike the medical ICU, rarely initiates mechanical ventilation for primary respiratory failure (e.g., pneumonia or chronic obstructive pulmonary disease exacerbation). SIMV is very similar to VC except that a patient initiated breath will not be given the prescribed tidal volume. The physician sets a respiratory rate and a prescribed tidal volume that will only be given if the ventilator initiates the breath. SIMV differs from the older IMV models by "synchronizing" a patient initiated breath that is very close to a ventilator initiated breath. For instance, if the patient initiates a breath very close to a predetermined ventilator breath, the ventilator will fully support this patient initiated breath with the prescribed tidal volume and not give the predetermined ventilator breath. The advantage to SIMV is that it is difficult to create breath-stacking or airway-trapping. However, if the patient

initiated breaths do not generate sufficient tidal volumes to maintain minute ventilation, the patient will quickly become tachypneic and fatigued. This can be avoided by adding pressure support ventilation (PSV) to each patient initiated breath to increase the tidal volumes.

Pressure Control Ventilation

Pressure control ventilation (PCV) is very similar to VC and SIMV except the ventilator will stop the inspiratory flow at a prescribed pressure rather than a prescribed volume. This mode of mechanical ventilation was developed to prevent high airway pressures when the patient has poor lung compliance.

Pitfalls of PCV

The inspiratory volumes are different with every breath in PCV so the minute ventilation also varies. Also the lung compliance can improve, which will increase the tidal volumes that can create volutrauma. The patient should be closely supervised when using PCV.

Pressure Support Ventilation

Pressure support ventilation (PSV) is a commonly used mode of mechanical ventilation used in all ICUs. It can be used as the primary mode or used in addition to another mode of mechanical ventilation. In a nutshell, PSV supports a patient initiated breath. In PSV, the ventilator delivers a flow-rate sufficient to reach the prescribed airway pressure and the ventilator will terminate the inspiration when the flow rate decreases by 25% which signifies that the patient has stopped inhaling. All breaths that are spontaneously initiated by the patient will be supported to the amount of pressure prescribed by the physician. PSV is an excellent method of weaning mechanical ventilation. The advantages of PSV are that the patient can determine their minute ventilation, which minimizes ventilator dysynchrony when compared to VC, SIMV, or PC.

Pitfalls of PSV

Since there are no mandatory ventilator breaths with PSV, hypoventilation can be problematic in patients on sedatives due to decreased respiratory drive.

Pressure Regulated Volume Control

Pressure regulated volume control (PRVC) is a complex mode of mechanical ventilation that is most often used in patients with poor lung compliance (acute lung injury or ARDS). It can be used with VC or SIMV. PRVC is a volume cycled mode (inspiratory flow stops at prescribed volume), which will constantly adjust the inspiratory flow rate during the inspiration of each delivered breath. The adjustment of the inspiratory flow rate allows more inspiratory volume at lower airway pressures. Similar to other volume cycled modes of mechanical ventilation (e.g., VC or SIMV), PRVC will stop the inspiratory flow if the peak airway pressure reaches a predetermined value.

Airway Pressure Release Ventilation

Airway pressure release ventilation (APRV) is often referred to as a newer mode of mechanical ventilation. It was actually first introduced in the late 1980s. Although many physicians struggle with understanding APRV, it is merely continuous positive airway pressure (CPAP) with occasional releases. It offers the advantage of allowing the patient to spontaneously breathe without additional inspiratory flow from the ventilator. Allowing spontaneous breathing offers many benefits. It decreases ventilator dysynchrony while improving oxygenation and cardiac output. There are many studies that reveal the improvement of oxygenation and cardiac output when compared to standard mechanical ventilation. However, despite these improvements there has been no proven survival benefit when using APRV. Also, the improved patient-to-ventilator interaction often requires less sedation.

High-Frequency Oscillation

High frequency oscillation (HFO) is used primarily as a rescue mode of mechanical ventilation in refractory hypoxemia seen in ARDS. This unconventional mode of mechanical ventilation improves oxygenation by maintaining an increased mean airway pressure (similar to APRV), which enables recruitment of collapsed alveoli. The constant mean airway pressure maintains alveolar recruitment, which reduces shunting and prevents high peak pressures. Like APRV, HFO significantly improves oxygenation without changing mortality.

Pitfalls of HFO

Only experienced providers should use HFO due to its complexity. The patient often has to be completely sedated secondary to the extreme discomfort experienced with this unconventional mode of ventilation. Hypercarbia (high CO_2) can be problematic due to the small tidal volumes seen in HFO.

Proportional Assist Ventilation

This newer mode of mechanical ventilation was developed to limit ventilator dysynchrony. In general terms, proportional assist ventilation (PAV) is a newer generation of PSV. PAV differs from PSV by adjusting the inspiratory flow-rate during each breath to attain the percentage of effort that is prescribed by the physician. The physician prescribes the amount of "work" that is done by the ventilator compared to the patient. The ventilator will calculate the "work" or energy in joules required for each inspiration. The ventilator will provide enough flow to match the prescribed "work." This mode should allow for rapid weaning and reduced ventilator dysynchrony. However, the available literature has not revealed an advantage over PSV.

Discontinuing Mechanical Ventilation

It is clear that prolonged intubation or mechanical ventilation is linked to increased mortality, morbidity, length

of stay, and costs; thus, it is important to extubate the patient when appropriate. Most authors would suggest that a 10% reintubation rate is appropriate. This number may be inflated for surgical patients since the ventilator is usually not for pulmonary dysfunction that is often seen in the medical ICU. It is also clear that reintubation in the ICU carries a significant increase in morbidity and mortality. These factors are why the decision for extubation is both important and difficult.

Factors to consider when contemplating extubation represent both pulmonary and nonpulmonary origins. The first consideration for extubation is to be sure the primary reason for intubation has been resolved. Other nonpulmonary contributors would include: neurologic status, ability to clear secretions, hemodynamic stability, nutrition, and acid–base status. The acid–base status is a very important consideration. The respiratory system is the first compensatory mechanism to correct metabolic acidosis/alkalosis. For instance, in metabolic acidosis the patient will become tachypneic in order to increase the pH. This tachypnea increases dead-space ventilation while also increasing energy expenditure in a patient that may have a predilection for respiratory fatigue. The opposite is true for metabolic alkalosis in which the primary compensation is hypoventilation.

There are many methods of weaning from mechanical ventilation. In 1995, Esteban et al. (15) compared four methods of weaning from mechanical ventilation. They revealed that patients managed with spontaneous breathing trials at least once daily were the best protocol for weaning. Ely et al. (16) later demonstrated that combining the daily wean screen with spontaneous breathing trials further decreased time of mechanical ventilation. Common measures used to determine the likelihood of successful extubation are displayed in Figure 5.1.

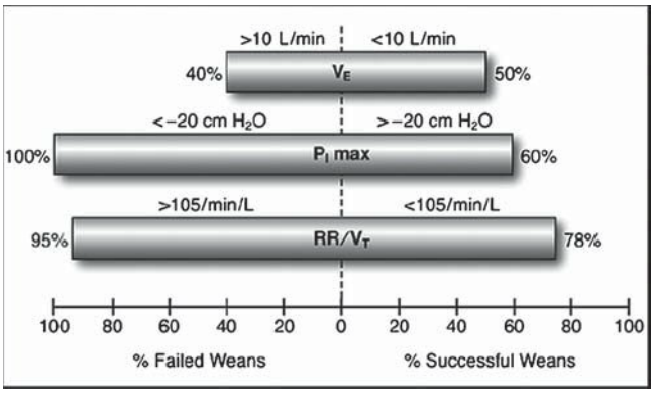

Figure 5.1 The predictive value of selected measurements obtained during spontaneous breathing. VE, minute ventilation; Pi_{max}, maximum inspiratory pressure; RR/VT, ratio of respiratory rate to tidal volume. (Data from Yang K, Tobin MJ. A prospective study of indexes predicting the outcome of weaning from mechanical ventilation. *N Engl J Med* 1991;324:1445–1450; Marino P. *The ICU book*, 3rd ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2007, with permission.)

Common Protocols (17) for Discontinuation of Mechanical Ventilation

1. Spontaneous daily awakening (18)
2. Wean screen (16)
3. Spontaneous breathing trials (19)
4. Pulmonary mechanics (see Table 5.3)

Timing of Tracheostomy

The optimal timing of tracheostomy in a patient receiving prolonged mechanical ventilation is controversial. A recent examination of the National Trauma Databank revealed large variations in the timing of tracheostomy during prolonged mechanical ventilation (20). In 1984, Whited (21) noticed subglottic damage from the endotracheal tube/cuff was evident at 7 days. A short time later, the National Association of Medical Directors of Respiratory Care recommended tracheostomy to be performed in patients that required mechanical ventilation greater than 3 weeks (22). Since that time, many observational studies have suggested early tracheostomy is beneficial. However, these studies have mixed results. One concern with the available literature is that many studies use different terminology to describe early versus late tracheostomy.

The perceived advantage of early tracheostomy would include: decreased sinusitis, decreased tracheal stenosis, decreased mechanical ventilation, decreased ventilator associated pneumonia (VAP), better secretion clearance, and decreased mortality. However, not all of these are supported by the literature and there is no evidence that early tracheostomy improves long-term mortality. A recent randomized controlled trial examined tracheotomy at 6 to 8 versus 13 to 15 days in 600 ICU patients (23). There were more VAPs in the 13- to 15-day group but this did not reach statistical significance ($p = 0.07$). This study also found the early group required less time on the ventilator and decreased ICU stay. There was no change in mortality at 28 days. Interestingly, 39% of patients that received a tracheostomy had a complication associated with its placement. The authors concluded, "considering that anticipation for tracheotomy of

TABLE 5.3 STEPS OF TROUBLESHOOTING A NONFUNCTIONING NGT

Make sure the NGT is on continuous suction and air port is unobstructed
Turn off suction
Flush the gastric tube with saline
Flush the air port with air
Put on continuous suction
Repeat steps 3 and 4
If unable to make the NGT functional. Notify the attending. Consider replacing the NGT, upsizing it to a larger size, or placing on intermittent suction

1 week increased the number of patients who received a tracheotomy, and more than one-third of the patients experienced an adverse event related to the tracheotomy, these data suggest that a tracheotomy should not be performed earlier than after 13 to 15 days of endotracheal intubation."

Percutaneous Versus Open Tracheostomy

The percutaneous dilational tracheostomy (PDT) was first introduced in the 1960s. It did not become popular until Ciaglia provided physicians with a better system to facilitate safe placement via a dilational technique. Since that time, the methods and experience with placing PDTs have enhanced its utilization. As physicians were learning this new technique, there proved to be a learning curve that was not without complications, which is well documented in the literature. One crucial addition to the method of PDT was the simultaneous use of bronchoscopy (24,25). The use of bronchoscopy has proven to prevent many of the major complications that were initially seen with PDT.

In 1999, a meta-analysis revealed the PDT had more complications than the open technique (26). However, a more recent large meta-analysis of 17 randomized controlled trials showed that PDT was superior to open tracheostomy (27). This study revealed less wound infections, bleeding, and mortality. The differences seen in these two large studies may be the time period in which they were performed. As stated above, the techniques and experience with the PDT have improved greatly over the past 25 years.

The cost difference between the two techniques may be dependent upon the location (ICU vs. operating room) in which they are performed. With the wide variety of techniques involving PDT among providers, it is difficult to assess the incidence of wound infections in clinical trials and it is likely that a smaller incision/dissection will provide lower wound infection rates. The one complication that is not completely understood is the rate of tracheal stenosis with the PDT. The incidence of tracheal stenosis following a PDT is not known. Many believe the PDT will often crush the anterior trachea, which produces a fracture of the tracheal rings. The inward displacement of the fractured rings may create a significant stenosis. A more proximal fracture occurring at the level of the first tracheal ring would be very likely to cause a symptomatic subglottic stenosis. In one postmortem study (28), patients with PDT demonstrated an anterior fracture to the tracheal rings, which produced significant stenosis in 11 of 12 patients. Another study examined the rate of tracheal stenosis after PDT by performing endoscopic examinations on 146 patients referred to a rehabilitation center. The authors found that 23.8% of patients who received PDT had greater than 50% stenosis compared to 7% who had an open tracheostomy (29). It is likely the tracheal stenosis rate is significantly higher with PDT, however, the rate of symptomatology exhibited by the stenosis is difficult to determine because of the low functional reserve of patients receiving a PDT.

Due to conflicting results of many randomized controlled trials, it is difficult to recommend which of the two techniques is superior. Therefore, the physician should use the technique in which they have the most experience. If the preferred technique is PDT, it should be performed under bronchoscopic guidance. Open tracheostomy is still the preferred technique for select patients with thyroid hyperplasia, short neck, tracheomalacia, obesity, previous neck operation, and for children (30).

MAINTAINING A FUNCTIONAL NASOGASTRIC TUBE

The nasogastric tube (NGT) was first placed by John Hunter in the 1600s to feed a patient. It was not until the early 1930s before physicians routinely used the NGT for gastric decompression. The current NGTs actually contain two separate lumens that are fixed together (Fig. 5.2). The large lumen is for the passage of gastric contents. The smaller (often blue) port is for air only. The sump NGT works by allowing continuous suction applied to the larger tube to pull air through the blue tube, which creates a continuous cycle of air being pulled from the atmosphere into the stomach and back into the wall suction. This constant flow of air prevents the tip of the NGT from suctioning directly on the mucosa causing ulceration/perforation. If air is not allowed through the air tube in a continuous manner, the tip of the NGT will suction directly on the mucosa and create ulceration and may lead to perforation. Therefore, nothing should ever obstruct the air tube and the NGT should always be on continuous suction. Common mistakes that obstruct the continuous flow of air include: intermittent suction, fluid in the air port, putting a cap on the blue port, and tying the blue tube in a knot. All of these increase the chance of the patient suffering a severe iatrogenic complication.

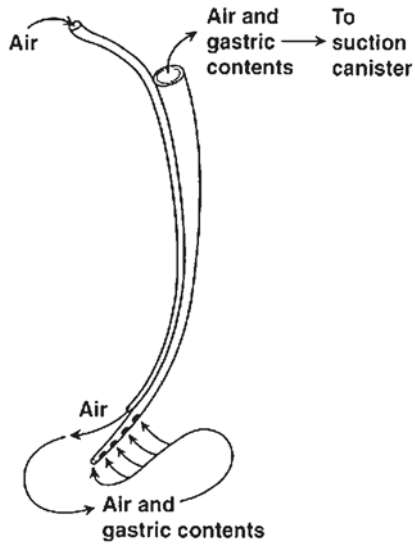

Figure 5.2 Nasogastric tube. (From Blackbourne LH. *Surgical recall*, 6th ed. Philadelphia, PA: Lippincott Williams and Wilkins, 2012, with permission.)

One way to know the NGT is not working properly (suctioning directly on the mucosa) is when gastric contents back up through the air tube (blue port). This simply means the NGT is not functional and the problem must be fixed to prevent iatrogenic mucosal injury. One problem is the described backup of gastric contents into air tube is considered a nuisance. In fact, the NGT companies have devised a one-way valve to prevent this from happening. This is a dangerous situation because it implies that it is OK to have a nonfunctional NGT on continuous suction. It is ill advised to allow any type of cap or one-way valve to be placed on the air tube. The backup of gastric contents is the easiest way to tell if the NGT is functional and not causing direct injury to the gastric mucosa. The steps for troubleshooting a nonfunctioning NGT are listed in Table 5.3.

OLIGURIA IN THE POSTOPERATIVE PERIOD

Oliguria in the postoperative period is very common and is generally defined as urine output of less than 0.5 mL/kg/h. There are many potential causes and the physician must quickly determine the correct diagnosis to direct appropriate treatment. The reported mortality associated with acute kidney injury (AKI, formerly called acute renal failure) varies but is routinely reported as approximately 50%. It is very important for the physician to remember that AKI is usually a secondary event. The predicted mortality or morbidity for AKI is likely more accurately represented by the process that caused the AKI.

There are many potential causes and they can be grouped into three categories: prerenal, intrarenal (intrinsic), and postrenal (Table 5.4).

TABLE 5.4 COMMON CAUSES OF AKI

Prerenal	Hypovolemia
	Decreased cardiac output
	Renal artery obstruction/stenosis
	Hepatorenal syndrome
	Medications (ACE inhibitors, NSAIDs, ARBs)
	Aortic dissection
Intrarenal	ATN
	Sepsis
	CIN
	Myoglobinuria
	Antibiotics (penicillin, sulfonamide, and allopurinol)
	Vasculitis
	Embolus
Postrenal	Urinary catheter obstruction
	Ureter obstruction
	Bladder

The diagnostic workup should be focused on the common causes of postoperative AKI. The most common postrenal cause of AKI is an obstructed urinary catheter, which can be easily diagnosed by flushing the urinary catheter with saline. After quickly ruling out the most common cause of postrenal obstruction, the focus should be to determine if the cause is prerenal or intrarenal. The most common cause of AKI in the postoperative period is acute tubular necrosis (ATN) from previous hypotension/hypovolemia. A careful review of the history combined with a thorough physical exam will often point to the correct diagnosis rather quickly. The diagnosis may then be confirmed while directing appropriate therapy. The most important category to quickly diagnose is prerenal, because the intervention will benefit other organ systems as well (i.e., if the kidneys are receiving decreased blood flow, so are the other organs).

The physical exam should focus on signs of perfusion. Signs of perfusion may be evident by warmth of peripheral tissues and strength of distal pulses. Auscultation of a new cardiac murmur or abdominal bruit may also be helpful. One should be careful of trying to measure intravascular volume based on patient change in weight or peripheral edema as these are very unreliable determinates of intravascular volume.

Laboratory and diagnostic data will help confirm the diagnosis. A renal ultrasound can be a valuable noninvasive diagnostic test that can rule out multiple diagnoses including: renal artery stenosis, infarction, and all postrenal causes of AKI. Important laboratory studies include: hemoglobin, serum and urine chemistry, urinalysis and urine microscopy. Other helpful laboratory studies include an arterial blood gas with a lactate to rule out acidosis or anaerobic metabolism (shock).

The most commonly used measure of renal function is serum creatinine. Creatinine is a byproduct of muscle breakdown and its production is not constant. Also, creatinine is filtered in the glomerulus and reabsorbed in the distal tubule. Therefore, the production and clearance make its accuracy in predicting AKI problematic in the acute setting and should be used with caution. The fractional excretion of sodium (FE_{Na}) has been considered a very accurate test to differentiate between prerenal disease and ATN. The accuracy of FE_{Na} has been recently questioned. A similar test, fractional excretion of urea (FE_{UN}), may be a better predictor of glomerular filtration. One study (31) revealed that FE_{UN} was more sensitive and specific for diagnosing prerenal AKI when compared to FE_{Na} (Table 5.5).

ATN is the most common cause of postoperative AKI. This is classically due to intraoperative or postoperative hypotension. The oliguria in ATN is usually seen after the hypotensive episode but the increase in serum creatinine can take days to weeks later. The hypotension causes ischemia of the proximal renal tubules, which creates sloughing of the tubular epithelium. As the dead cells slough, they create a blockage that will cause a backup of urine. As the urine backs up into the glomerulus, the glomerular

TABLE 5.5 PRERENAL VERSUS ATN

	Prerenal	ATN
Urine Na	<20	>40
BUN/Creatinine	>20	<10
Urine specific gravity	>1.020	<1.010r
Urine osmolality	>500	<250
$FE_{Na} = U_{Na} \times P_{Cr} \div U_{Cr} \times P_{Na}$	<1%	>1%
$FE_{UN} = U_{UN} \times P_{Cr} \div U_{Cr} \times P_{UN}$	<35%	>35%

filtration rate decreases. Urine microscopy will reveal multiple granular casts. A recent study in 2008 reveals that examination of urine microscopy accurately differentiated ATN from prerenal AKI (32). The treatment of ATN is supportive care focusing on the avoidance of electrolyte abnormalities and hypovolemia.

ANALGESIA

Virtually all postoperative patients require analgesia and commonly used analgesics in the ICU during the postoperative period are described. The indications and route of administration is beyond the scope of this chapter.

OPIATES

This category of medications is derived from the opium poppy plant and has been used for centuries. Many patients and physicians commonly associate opioids with addiction and may limit the appropriate dosing schedules despite evidence suggesting that opioid addiction in hospitalized patients is extremely rare (33). The classic opioid is morphine. Opioids act on the μu opioid receptor (μu stands for "morphine"). The majority of μu receptors are found in the brain and spinal cords. Although the most potent effect of opioids is analgesia, they also cause some degree of sedation, decreased respiratory drive, and hypotension. The majority of these side effects can be avoided at lower doses. The incidence of these side effects among opiates varies between medications. Despite the side effect of sedation at high doses, opiates do not cause amnesia. Most of the opiates are metabolized in the liver and then excreted by the renal system. Several reports suggest that opiates with active metabolites (morphine and codeine derivatives) cause significant narcosis and respiratory depression when used during renal insufficiency (34,35).

MORPHINE AND MEPERIDINE

In a 2007 survey, morphine was the most frequently used opiate in the ICU (36). However, morphine and meperidine have many side effects that other available opiates do not have. Morphine and meperidine have active metabolites that limit prolonged administration in the setting of renal insufficiency. Some of the metabolites of the two medications are more potent than the parent compound. The dose of morphine and meperidine should be reduced to 50% in the setting of renal insufficiency. Morphine and meperidine also cause histamine release which produces hypotension. This hypotensive effect is most exaggerated with large doses that are given rather quickly. Meperidine is used much less frequently than morphine due to its side effects (including euphoria) and the active metabolite normeperidine. Naloxone will reverse the respiratory depression caused by most opioid drugs but will not alter this effect when caused by normeperidine.

FENTANYL

Fentanyl is a synthetic opiate that has 100 times the potency of morphine. It also demonstrates a shorter time of onset and half-life when compared to morphine. Fentanyl does not activate histamine release and is the opioid of choice during relative hypotension making fentanyl a more attractive choice than other opiates in the ICU. It can also be used in renal insufficiency because it has no active metabolites. However, it is much more lipid soluble than morphine, which can contribute to accumulation and prolonged effect when used for extended periods of time or in patients with obesity.

HYDROMORPHONE

Hydromorphone is a semisynthetic derivative of morphine. Therefore, it demonstrates many of the same side effects as morphine. Hydromorphone has active metabolites but does not exhibit histamine release seen with morphine. Because of the active metabolites, the half-life of hydromorphone can increase by 20-fold with renal insufficiency. Due to its potency and half-life, it is often used in patients with a high pain tolerance in patients without liver or renal insufficiency (Table 5.6).

SEDATIVES IN THE ICU

The use of sedatives in the ICU have changed dramatically over the past decade. It was once thought to be cruel to allow patients to remain awake while receiving mechanical ventilation. Despite the perceived advantages, continuous sedative infusions for critically ill patients have been shown to increase the duration of mechanical ventilation and length of intensive care stay (38,39). Many studies have shown a linear relationship between ventilator days and ICU length of stay with mortality. More recently, there has been a large interest in the relationship between the overuse of sedation and delirium. High doses of benzodiazepines have been shown to cause delirium and one study described a 100% transition rate to delirium with

TABLE 5.6 COMMONLY USED OPIATES FOR ADULTS IN THE ICU

Medication	Strength[a]	Route	Typical Dose[b]	Typical Frequency[b]	Active Metabolite	Histamine Release
Morphine	1	IV, IM, SQ	0.1–0.2 mg/kg	q3h	Yes	Yes
Meperidine	0.1	IV, IM, SQ	1–2 mg/kg	q2h	Yes	Yes
Fentanyl	100	IV, IM, SQ	1–2 µg/kg	q1h	No	No
Hydromorphone	5	IV, IM, PO	1–2 mg	q4h	Yes	No

[a]The strength is based on equivalency to intravenous morphine.
[b]The appropriate dose and frequency will vary significantly between patients. The physician should always start at the lower dose and titrate to pain scores (37).

continuous lorazepam infusions (40). In 2004, Ely et al. (41) reported a significant increase in mortality in patients with delirium. This study and others have prompted a recent flurry of evidence suggesting that the routine use of continuous sedation for mechanical ventilation is not needed and increases adverse events including death.

Benzodiazepines

Benzodiazepines are $GABA_A$ agonists. GABA is the major inhibitory neurotransmitter mediating the inhibitory actions of neurons in the brain and spinal cord. Although it increases GABA throughout the body, the most prominent effects are on the central nervous system. The notable effects include: sedation, anxiolytic, anterograde amnesia, muscle relaxation, and anticonvulsant activity. Benzodiazepines do not tend to cause cardiovascular or respiratory problems at therapeutic doses unless they are given in addition to narcotics or other sedatives. They have no intrinsic analgesic properties. However, they are known to potentiate the pain relief when used in combination with opiates. Most benzodiazepines undergo hepatic metabolism followed by renal excretion and should be used with caution in patients with liver or kidney disease. There are three main types of benzodiazepines used in the ICU. They are diazepam, lorazepam, and midazolam (see Table 5.7).

Diazepam

Diazepam is a long-acting fat-soluble benzodiazepine that is not frequently used in the ICU because of its unpredictable absorption and active metabolites. Therefore, it is rarely used in the ICU as a bolus and should not be used as an infusion. Diazepam also contains the preservative propylene glycol, which can cause metabolic acidosis with accumulation.

Lorazepam

Lorazepam has the lowest fat solubility of the benzodiazepines listed here. This property creates a slower onset of action with a prolonged duration. However, its metabolism by glucuronidation makes the clearance the most predictable in the setting of liver dysfunction. Like diazepam, it contains propylene glycol that can accumulate with prolonged use.

Midazolam

Midazolam has a fast onset of action with the shortest half-life of the benzodiazepines frequently used in the ICU. It is this quality that makes it the most frequently used benzodiazepine infusion. However, the effective half-life can increase significantly with prolonged infusion. Like diazepam, midazolam also has an active metabolite that may potentiate its accumulation during renal failure.

TABLE 5.7 BENZODIAZEPINES COMMONLY USED IN THE ICU

Medication	Onset (min)	Half-Life (h)	Active Metabolite	Bolus Dose (mg)	Infusion Dose[a]
Diazepam	<5	20–40	Yes	5–10	Not recommended
Lorazepam	<20	10–20	No	1–2	0.5–10 mg/h
Midazolam	<5	3–5	Yes	1–2	0.5–10 mg/h

[a]Maximum infusion doses should be based on individual institutional protocols.

Propofol

Propofol is a very potent fat-soluble sedative that has rapid onset and rapid clearance when used as a bolus. These properties have made it the induction agent of choice for many anesthesiologists. As with any fat-soluble medication, prolonged use as an infusion can create accumulation. The mechanism is not completely understood but it most likely potentiates GABA. It produces sedation and amnesia but does not exhibit analgesic properties. It is hepatically conjugated to an inactive form, which makes it an attractive choice in the setting of renal insufficiency. Despite all of its good qualities, it can demonstrate severe side effects. The most common is hypotension. Hypotension is most often seen with a large bolus but can also be present with low-dose infusions. Because propofol is formulated in an emulsion containing purified egg phospholipids, the sedative should not be used if the patient has an allergy to eggs. However, the most feared complication is propofol-related infusion syndrome (PRIS). PRIS is a rare complication associated with high doses or prolonged use greater than 48 hours. Although it is rare (probably <1%), it is often deadly. Symptoms include metabolic acidosis, rhabdomyolysis, hypotension, and dyslipidemia. There is no effective treatment other than discontinuing the propofol infusion and providing supportive care. Therefore, for patients requiring escalating doses or infusion greater than 48 hours should be closely followed for hyperlipidemia and lactic acidosis.

Dexmetomidine

Dexmetomidine is a centrally acting alpha-2 agonist that provides sedation and anxiolysis without respiratory depression. A recent double-blinded randomized controlled trial compared the use of dexmetomidine and midazolam in the ICU (42). It revealed that dexmetomidine significantly reduced delirium by 20% and ventilator use by 2 days when compared to midazolam. However, it did exhibit more bradycardia while patients with midazolam had tachycardia and hypertension more frequently. The sedative and sympatholytic effects without respiratory depression make this a very attractive option in postoperative patients. However, this medication is very expensive making it difficult for many institutions to justify the costs.

THE USE OF PERIOPERATIVE BETA BLOCKER PROPHYLAXIS IN THE ICU

Perioperative beta blockade has been the standard of care in the ICU for many years but the recent guidelines have changed. Several small studies published in the late 1990s suggested that prophylactic beta blockade may be useful in preventing cardiovascular complications in the perioperative period (43,44). Despite the potential flaws of these studies (45), perioperative beta blockers became the standard of care for patients with cardiovascular risk factors and are still used as benchmarks for defining the quality of care given to surgical patients. Using a beta blocker to decrease myocardial ischemia in the noncardiac surgical patient seems to make sense. The pathologic rise in catecholamines following a major surgical procedure causes excess tachycardia and increased myocardial oxygen demand.

In 2006, the metoprolol after vascular surgery (MAVS) study did not reveal a benefit for beta blockade in high-risk vascular surgery patients and the group that received the beta blocker had significantly more bradycardia and hypotension that required treatment (46). The results of the MAVS trial and others (47) not only questioned the benefit of beta blocker prophylaxis, but also revealed potential side effects. This led to the POISE trial, which was published in 2008 (48). This randomized controlled trial enrolled over 8,000 patients with evidence of a major cardiovascular risk factor to examine the effect of metoprolol that was started preoperatively and continued for 30 days after surgery. Although the metoprolol group had fewer myocardial infarctions, the drug also resulted in a significant excess risk of death, stroke, and clinically significant hypotension and bradycardia. The POISE trial called into question the safety of routine perioperative beta blockers. In 2008, the American College of Cardiology and American Heart Association released a focused update to the previously released 2007 guidelines for perioperative beta blocker therapy (49). Table 5.8 shows the perioperative risk of a cardiovascular complication for different surgical procedures. Table 5.9 shows the changes in recommendations for beta blocker prophylaxis from the previous guidelines.

TABLE 5.8 CARDIAC RISK STRATIFICATION FOR NONCARDIAC SURGICAL PROCEDURES[a]

Risk Stratification	Procedure Examples
Vascular (reported cardiac risk often >5%)	Aortic and other major vascular surgery
	Peripheral vascular surgery
Intermediate (reported cardiac risk generally 1%–5%)	Intraperitoneal and intrathoracic surgery
	Carotid endarterectomy
	Head and neck surgery
	Orthopedic surgery
	Prostate surgery
Low (reported cardiac risk generally <1%)	Superficial procedures
	Endoscopic procedures
	Breast surgery
	Ambulatory surgery

[a]Modified from the ACC and AHA Guideline (49).

TABLE 5.9 CHANGES MADE IN 2008 FROM PREVIOUS GUIDELINES ON PERIOPERATIVE BETA BLOCKADE (49)

2007 Perioperative Guideline Recommendations	2009 Perioperative Focused Update Recommendations	Comments
Class I evidence		
Beta blockers should be continued in patients undergoing surgery who are receiving beta blockers to treat angina, symptomatic arrhythmias, hypertension, or other ACC/AHA Class I guideline indications. (Level of evidence: C)	Beta blockers should be continued in patients undergoing surgery who are receiving beta blockers for treatment of conditions with ACCF/AHA Class 1 guideline indications for the dr ugs. (Level of evidence: C)	2007 recommendation remains current in the 2009 update with revised wording
Beta blockers should be given to patients undergoing vascular surgery who are at high cardiac risk owing to the finding of ischemia on the preoperative testing. (Level of evidence: B)		Deleted/combined recommendation (class of recommendation changed from I to IIa for patients with cardiac ischemia on preoperative testing).
Class IIa		
Beta blockers are probably recommended for patients undergoing vascular surgery in whom preoperative assessment identifies coronary heart disease. (Level of evidence: B)	Beta blockers titrated to heart rate and blood pressure are probably recommended for patients undergoing vascular surgery who are at high cardiac risk owing to coronary artery disease or the finding of cardiac ischemia on preoperative testing. (Level of evidence: B)	Modified/combined recommendation (working revised and class of recommendation changed from I to IIa for patients with cardiac ischemia on preoperative testing)
Beta blockers are probably recommended for patients in whom preoperative assessment for vascular surgery identifies high cardiac risk, as defined by the presence of more than one clinical risk factor. (Level of evidence: B)	Beta blockers titrated to heart rate and blood pressure are reasonable for patients in whom preoperative assessment for vascular surgery	Modified recommendation (level of evidence changed from B to C)
Beta blockers are probably recommended for patients in whom preoperative assessment identifies coronary heart disease or high cardiac risk, as defined by the presence of more than one clinical risk factor, who are undergoing intermediate risk or vascular surgery. (Level of evidence: B)	Beta blockers titrated to heart rate and blood pressure are reasonable for patients in whom preoperative assessment identifies coronary artery disease or high cardiac risk, as defined by the presence of more than one clinical risk factor, who are undergoing intermediate risk surgery. (Level of evidence: B)	2007 recommendations remain current in 2009 update with revised wording.
Class IIb		
The usefulness of beta blockers is uncertain for patients who are undergoing either intermediate-risk procedures or vascular surgery, in whom preoperative assessment identifies a single clinical risk factor. (Level of evidence: C)	The usefulness of beta blockers is uncertain for patients who are undergoing either intermediate-risk procedures or vascular surgery in whom preoperative assessment identifies a single clinical risk factor in the absence of coronary artery disease. (Level of evidence: C)	2007 recommendations remain current in 2009 update with revised wording
The usefulness of beta blockers is uncertain in patients undergoing vascular surgery with no clinical risk factors who are not currently taking beta blockers. (Level of evidence: B)	The usefulness of beta blockers is uncertain in patients undergoing vascular surgery with no clinical risk factors who are not currently taking beta blockers. (Level of evidence: B)	
Class III		
Beta blockers should not be given to patients undergoing surgery who have absolute contraindications to beta blockade. (Level of evidence: C)	Beta blockers should not be given to patients undergoing surgery who have absolute contraindications to beta blockade. (Level of evidence: C)	2007 recommendations remain current in 2009 update with revised wording.
	Routine administration of high-dose beta blockers in the absence of dose titration is not useful and may be harmful to patients not currently taking beta blockers who are undergoing noncardiac surgery. (Level of evidence: B)	New Recommendation

TREATMENT OF ALCOHOL WITHDRAWAL SYNDROME

The incidence of alcohol withdrawal syndrome (AWS) after abrupt discontinuation of alcohol is variable but can be as high as 50%. Symptoms often follow a continuum starting with tremulousness and ending with delirium tremens (DTs). The term "DTs" is often thought to be synonymous with AWS. This is incorrect. It is rare that the symptoms of AWS progress to this magnitude. DTs are the last stage of AWS and carry significant mortality. The key to diagnosing DTs is the combination of hyperadrenergic activity and a change in sensorium (Table 5.10).

Chronic alcohol ingestion leads to enhanced activity of the inhibitory neurotransmitter GABA. The neurologic system compensates by upregulating *N*-methyl D-aspartate excitatory receptors to balance the affects of enhanced GABA. Therefore, abruptly removing the alcohol also decreases GABA to cause an excitatory and hyperadrenergic state causing symptoms of AWS. Therefore, the common treatment modalities for AWS target the GABA receptors.

Currently, benzodiazepines are the best treatment for AWS. The type of benzodiazepine does not seem to matter, so the choice should be based on the pharmacokinetics of the medication. There are many studies examining various medications (including alcohol) as prophylactic agents to prevent AWS. The results are mixed at best. Many show no evidence that alcohol or benzodiazepines are effective at preventing AWS and it appears that symptom-driven dosing is better than scheduled prophylactic dosing (50,51). These studies reveal that symptom-driven treatment requires less benzodiazepine administration, a shorter duration of treatment, and up to 40% of patients never require any treatment. This method seems to be the current trend for many ICUs. However, the prevention and/or treatment of AWS at your institution will likely depend on the beliefs and individual interpretation of the available data. For more information on AWS, a recent review of AWS in the ICU was published in *Critical Care Medicine* (52).

TABLE 5.10 CONTINUUM OF SYMPTOMS IN AWS

Minor Withdrawal (24–72 h)
- Anxiety
- Diaphoresis
- Fluctuating tachycardia
- Mild cognitive impairment

Major Withdrawal (24–72 h)
- Sustained tachycardia
- Confusion

DTs (72–96 h)
- Severe tachycardia
- Severe hypertension
- Fever
- Agitation
- Hallucinations

Note: Isolated seizures and hallucinations without hyperadrenergic activity generally occur at 24–48 hours and are associated with AWS but do not carry the same mortality as DTs.

Gastric Acid Suppression

Gastric stress ulcers are not uncommon in the ICU. However, only a small percentage of these ulcers produce significant bleeding. The reported incidence of gastric stress ulceration varies significantly. This is likely because of the difference in the mechanism of diagnosis and study population presented in the literature. However, the incidence of stress ulcers may be up to 15% in high-risk patients. Patients with stress ulcers and significant bleeding can have mortality rates up to 45%. Therefore, prevention of stress ulcers in the ICU is important. The perception that all ICU patients need prophylaxis is not correct. A large multicenter prospective study revealed only two major risk factors for significant gastrointestinal bleeding in the ICU. They included the use of mechanical ventilation greater than 48 hours and coagulopathy (odds ratio of 15.6 and 4.3, respectively) (53). The incidence of significant bleeding was about 3% with one or both of these risk factors compared to 0.1% with neither risk factor. Large burns and neurologic injuries have long been considered high risk for stress ulcers. Many of the larger trials excluded these injuries because of their high risk. So many providers still consider these factors as high risk for developing stress ulcers.

There are many options for stress ulcer prophylaxis. Currently, the standard of care is the use of proton pump inhibitors (PPI) or histamine receptor blockers (H_2 blockers). One large meta-analysis revealed no significant difference in ulceration between the PPIs and H_2 blockers (54). However, many studies suggest that a PPI may be slightly better than H_2 blockers. Both of these drug classes seem to increase the rate of VAP. The mechanism of VAP is likely linked to gastric bacterial overgrowth from the increase in gastric pH. Esophageal reflux and microaspiration in the setting of gastric bacterial overgrowth leads to colonization of esophageal and tracheal lumens with pathogenic bacteria. PPIs may have a slight increase in VAP rates compared to H_2 blockers, although not significantly different. The cost of H_2 blockers tend to be much less than PPIs. Therefore, many intensivists use H_2 blockers instead of PPIs unless the patient is on a PPI prior to hospitalization. There have also been recent suggestions that PPIs may cause an increase in *Clostridium difficile* (CDif) colitis and other infections (55,56). Other prophylactic medications include sucralfate and traditional antacids. Sucralfate is a mucosal coating agent that is delivered via NGT four times per day. It is considered inferior to PPI and H_2 blockers but has a lower incidence VAP. Sucralfate also must be used carefully in patients with renal failure due to aluminum toxicity. Very importantly, sucralfate should not be used in combination with H_2 blockers and other select medications due to the inhibition of absorption.

Gastric feeding has also been shown to decrease stress ulcers without the use of antacids. One observational study of burn patients revealed that early gastric feeding resulted in decreased ulceration compared to H_2 blockers alone (57). This study also revealed an increase in mortality in the group that received both early gastric feeds plus a H_2 blocker. However, this study population consisted of both high- and low-risk patients. Therefore, one should be careful interpreting the results and many physicians feel that early gastric feeds should not prevent the use of H_2 blockers or PPIs until further evidence is available. This is, however, another great reason to resume enteral nutrition as soon as possible.

PPIs or H_2 blockers should be first line agents for stress ulcer prophylaxis. The physician must weigh the risks, benefits, and costs associated with each to determine which medication should be used. The most important consideration is to only give stress ulcer prophylaxis when needed and discontinue the prophylaxis when appropriate. See Table 5.11 for indications for stress ulcer prophylaxis in the ICU.

Contrast-Induced Nephropathy

The concern about contrast-induced nephropathy (CIN) is warranted due to the high prevalence of renal insufficiency seen in the ICU. CIN is likely due to medullary vasoconstriction and direct cytotoxic/osmolar injury to the proximal tubules. This injury is considered immediate, so the only potential treatment is prevention. Therefore, dialysis before or after the contrast-load is not useful.

The rate of CIN varies according to each patient. There are many risk factors that are routinely associated with CIN that have not proven to be independent risk factors throughout the literature (see Table 5.12). It appears the most predictive risk factors for CIN are creatinine > 1.5 mg/dL and diabetes. Patients with this combination can have CIN in over 50% of cases.

TABLE 5.11 INDICATIONS FOR STRESS ULCER PROPHYLAXIS IN THE ICU[a]

Independent Predictors
Coagulopathy: Platelet count <50,000, INR > 1.5, or PTT > 2× control
Mechanical ventilation >48 h
Minor Predictors
Traumatic brain injury
Spinal cord injury
Burn >30%
Sepsis
Previous gastric ulcer within past year
Prolonged ICU stay
Corticosteroid therapy
Treatment
All ICU patients with at least one independent predictor or two minor predictors should receive stress ulcer prophylaxis

[a]Modified from ASHP Guidelines (58).

TABLE 5.12 RISK FACTORS FOR CIN[a]

Patient Related

Contrast volume

[a]Modified from Pannu N, Wiebe N, Tonelli M. Prophylaxis strategies for contrast-induced nephropathy. *JAMA* 2006;295(23):2765–2779.

The available data regarding the appropriate prophylactic treatment is conflicting. However, it is clear that increasing urine flow is beneficial. Therefore, any patient at risk for CIN should have intravenous volume expansion immediately prior and during contrast injection. It is not clear what type of intravenous infusion should be used to prevent AKI. However, it appears that isotonic solutions are more successful than hypotonic solutions at preventing CIN (59). Other popular strategies include administration of sodium bicarbonate or *N*-acetylcysteine (NAC).

Sodium bicarbonate ($NaHCO_3$) administration provides both alkalinization of the urine and provides intravascular volume expansion from the sodium. The alkalinization is thought to prevent free radical injury to the renal tubules. The most commonly used method of administration of $NaHCO_3$ is by adding 3 ampules of $NaHCO_3$ to 1 L of free water. Each ampule contains 50 mEq of Na^+ and 50 mEq of HCO_3. Adding 3 ampules of $NaHCO_3$ to 1 L of free water will create a relatively isotonic fluid. There are many randomized controlled trials examining the administration of $NaHCO_3$. The results in a few of the studies are equivalent, although the majority of studies reveal better outcomes compared to isotonic fluid administration. Thus, an isotonic $NaHCO_3$ solution should be provided when concerned for CIN *in lieu* of isotonic intravenous fluids alone unless otherwise contraindicated.

NAC is the most commonly studied intervention to prevent CIN. NAC is used for a variety of medical conditions including: pulmonary mucous retention, Tylenol toxicity, and CIN. The proposed mechanisms to prevent CIN are its antioxidant properties combined with the enhancement of the vasodilatory effects of nitric oxide. The results of studies examining the effect of NAC on CIN are mixed (60). However, due to the cost and safety profile of the medication, most authors suggest using oral NAC. This requires

beginning the administration of NAC up to 24 hours prior to giving the contrast agent. Due to the toxicity of the intravenous form, only the oral form of NAC should be used.

There are many contrast agents available to the radiologist. The incidence of AKI depends on the osmolality of the agent. The older ionic contrast agents have very high osmolalities, where the newer nonionic agents are closer to iso-osmolar. Although there are few comparisons between contrast agents, it appears the newer generation agents with lower osmolar gradients produce less CIN. The available literature suggests the contrast agents with lower osmolalities provide the most benefit when the creatinine is greater than 1.5 mg/dL with the presence of diabetes.

In summary, the only treatment for CIN is prevention. Each patient with renal insufficiency should be carefully examined for risk factors of CIN. Hyperosmolar contrast agents, dehydration, and medications that limit the glomerular filtration rate (ACE inhibitors, NSAIDS, etc.) should be avoided in high-risk patients if possible. There is a limited role for dialysis or diuretics. Although the literature is not completely clear, it appears that isotonic $NaHCO_3$ infusions are superior to isotonic saline alone in preventing CIN. The use of NAC may be helpful but should not replace isotonic $NaHCO_3$ infusions. (See Fig. 5.3 for a standard prevention strategy.)

Clostridium Difficile Colitis

CDif colitis is a commonly seen disease process in any ICU. The mortality of CDif colitis can be up to 30% in critically

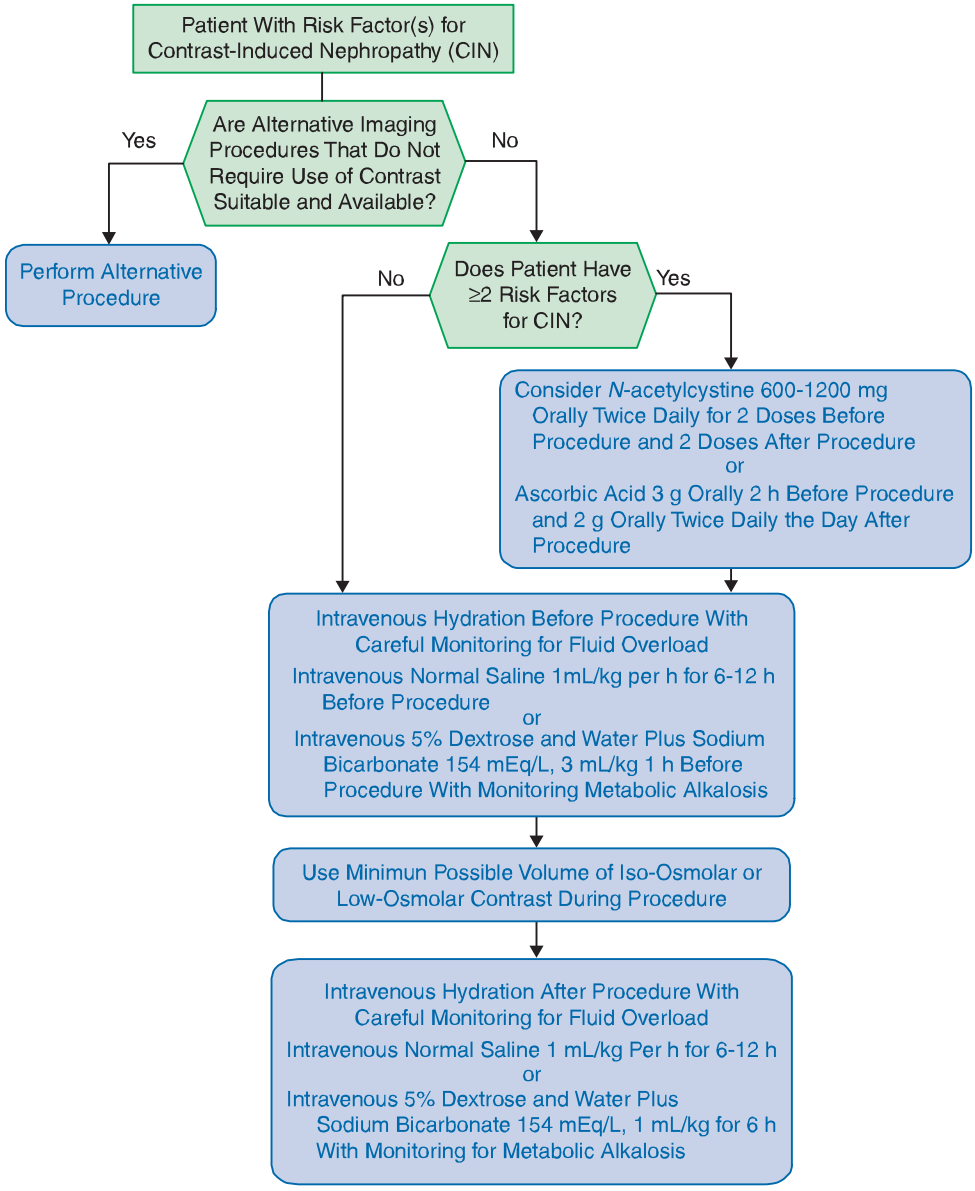

Figure 5.3 Strategy for management of patients with risk factors for contrast-induced neuropathy. (From Pannu N, Wiebe N, Tonelli M. Prophylaxis strategies for contrast-induced nephropathy. *JAMA* 2006;295(23):2765–2779.)

ill patients. The most common etiology of CDif colitis is from antibiotic administration. Although it is commonly secondary to long-term antibiotics, it can originate from a single dose of perioperative antibiotics.

CDif colitis is defined by the Centers for Disease Control as the passage of ≥3 loose stools per day and a positive diagnostic test or visualization of pseudomembranous colitis. The current methods of diagnoses are more accurate. The newer real-time stool PCR assay used to detect the toxin B gene are over 90% accurate. Therefore, empiric treatment with a negative PCR test should be rare. Stool testing should be performed prior to initiation of antibiotics. Stool examination for WBCs is not sensitive or specific for CDif and should be avoided.

The treatment of CDif colitis depends on its severity (see Table 5.13). Oral metronidazole is considered first line for uncomplicated disease and oral vancomycin is reserved for severe disease, pregnancy, and the second recurrent episode. The efficacy of intravenous metronidazole is not known and there is no role for intravenous vancomycin. Surgical intervention (i.e., colectomy) should be considered EARLY for patients who are hemodynamically unstable.

The rate of recurrence is not known. Historically, up to 25% can present with at least one episode of recurrence. This is most frequently due to failure to eradicate spores or acquisition of a new strain and can occur several weeks following the initial treatment. The first recurrence should be treated the same as the initial episode unless more severe. The second recurrence should be treated with oral vancomycin.

Prophylaxis against CDif only includes avoidance of offending agents. There is no role for prophylactic metronidazole. This may increase the incidence of CDif colitis while also increasing the resistant strains of CDif. Antibiotics that commonly cause CDif colitis are clindamycin, cephalosporins, and fluoroquinolones.

Perhaps the most important consideration in patients with CDif colitis in an ICU is infection control. Preventing the spread of CDif is very important. This highly infectious condition is spread easily by contact. Therefore, all patients with CDif colitis should be on contact isolation. The physician should wash their hands with soap and water before and after entering the patient room. The commonly used alcohol-based hand sanitizers are not useful for CDif spores.

Atrial Fibrillation

Atrial fibrillation (Afib) is a common complication seen in any ICU. The incidence in the postoperative patient varies according to the operation performed. There is a large amount of literature concerning postoperative cardiac and thoracic patients. However, the available evidence for noncardiothoracic surgical patients is scant. The incidence of atrial tachyarrhythmias can be seen in up to 50% of patients after cardiac surgery and 30% following thoracic

TABLE 5.13 CLINICAL MANIFESTATIONS AND TREATMENT FOR *CDif* INFECTION (61,62)

Infection Severity	Clinical Manifestations	Treatment[a]
Asymptomatic carriage	CDif antigen or PCR positive without diarrhea, ileus, or colitis	Do not treat. Treatment could promote resistance and recurrent disease
Mild or moderate	PCR positive with diarrhea but no manifestations of severe disease	Metronidazole 500 mg PO q8h
Severe	PCR positive with diarrhea and one or more of the following attributable to CDif infection: WBC > 15,000 ↑ creatinine >50%	Vancomycin solution 125 mg PO q6h. Solution is preferred over capsules
Severe complicated	Severe disease (see above) plus one of the following: Hypotension Ileus Colitis on CT scan Toxic megacolon Perforation Require ICU admission	Obtain surgical and infectious disease consultation. Vancomycin solution 500 mg PO q6h PLUS metronidazole 500 mg IV q8h. If unable to tolerate oral therapy or signs of ileus: Vancomycin 500 mg in 100 mL normal saline as retention enema PLUS metronidazole 500 mg IV q8h

[a]Duration of treatment should be at least 10–14 d.
Note: This table was modified from the Johns Hopkins Antibiotic Guidelines (61) with permission. This table can also be viewed at www.hopkinsmedicine.org/amp.

TABLE 5.14 STROKE RISK IN AFIB ACCORDING TO $CHADS_2$ SCORE

	Points		$CHADS_2$ Score	1-Y Stroke Rate (%)	Treatment
CHF	1		6	13.7	*High Risk*
Hypertension	1		5	12.3	Warfarin
Age > 75 y	1	SUM	4	10.9	*Moderate Risk*
Diabetes	1		3	8.6	Warfarin or Aspirin
Stroke	2		2	4.5	*Low Risk*
			1	2.2	Aspirin
			0	0.8	

This table was modified from Ref. 67.

surgery. The incidence following noncardiothoracic surgery is below 10% in most studies. This difference in the incidence of Afib between these operations likely suggests a different pathogenesis. In normal patients, the predominant regulator of heart rate is the vagal tone. The most probable cause of Afib in the noncardiothoracic patient is a sympathetic overstimulation from the stress response to surgery. The documented elevation of catecholamines causes overstimulation of the myocardial excitability, which creates tachycardia. Since the body does not need the increase in heart rate, it will try and slow itself by increasing vagal tone. The slowing of electrical conduction (vagal stimulus) during increased myocardial excitability (catecholamine surge) creates a perfect setup for ectopic foci and reentry phenomena. The prevention of Afib in the noncardiothoracic patient is not well studied. At this time, there is no evidence to suggest prevention is helpful, and in many cases, it is harmful. There is only one randomized controlled trial examining the pharmacologic treatment of postoperative Afib. This RCT found esmolol superior to diltiazem in the treatment of atrial tachyarrhythmias in the hemodynamically stable patient (63). Although many intensivists may use amiodarone acutely for Afib, the efficacy and side-effect profile of amiodarone is mixed in the available retrospective trials (64,65). With the available evidence, esmolol should be the first line agent for postoperative Afib in the hemodynamically stable noncardiothoracic patient. Amiodarone should be reserved for cases where a beta blocker is contraindicated (i.e., obstructive airway disease, etc.).

Following conversion to a sinus rhythm, continued treatment is not warranted unless otherwise indicated. It is uncommon that postoperative Afib does not convert to a sinus rhythm within 48 hours but occasionally this is the case. In this instance, the decision must be made for either rate or rhythm control with or without anticoagulation. The decision for rate versus rhythm control should be made by the cardiologist. The current literature regarding rate versus rhythm control would suggest they have similar rates of embolic events. Therefore, many cardiologists lean toward rate control unless rhythm control is otherwise indicated. The more important question for the physician is whether to start anticoagulation. Every patient with Afib does not need anticoagulation. The risk of stroke in patients with Afib is quite low in most studies. For example, the Framingham study revealed an annual stroke rate of 1.3% (66). Most cross-sectional studies reveal an annual stroke risk of less than 3%. Therefore, any treatment (i.e., anticoagulation) must have a favorable side-effect profile that does not exceed the benefit of the medication. The risks associated with embolic events are well documented. One of the more commonly used scoring systems to stratify the risk of embolization is the $CHAD_2$ score (67) (see Table 5.14). Although there have been modifications to the $CHAD_2$ score that improve the prediction of embolic events with Afib, the improved accuracy is not enough for the otolaryngologist to remember the more complicated formulas. Therefore, we recommend using the $CHAD_2$ Score for predicting embolic events with Afib (Table 5.14).

HIGHLIGHTS

- The three factors that determine the delivery of oxygen to the peripheral tissues are cardiac output, hemoglobin, and oxygen saturation.
- Prolonged use of mechanical ventilation has potential serious complications.
- The optimal timing of tracheotomy with use of prolonged mechanical ventilation is not known; however, strong consideration should be given after 2 weeks.
- The open and percutaneous tracheotomies both have advantages and disadvantages. The optimal surgical technique likely depends most on the surgeons experience with each method.
- ATN is the most common cause of postoperative renal failure. The treatment of ATN is supportive care focusing on the avoidance of electrolyte abnormalities and hypovolemia.

- Symptom-driven treatment of AWS requires less benzodiazepine administration, a shorter duration of treatment, and up to 40% of patients never require any treatment.
- The only independent risk factors for stress ulcer hemorrhage in the ICU are mechanical ventilation greater than 48 hours and coagulopathy.
- It appears that isotonic $NaHCO_3$ infusions are superior to isotonic saline alone in preventing CIN. The use of NAC may be helpful but should not replace isotonic $NaHCO_3$ infusions.
- Oral metronidazole is superior to intravenous metronidazole for the treatment of CDif colitis. Oral vancomycin should be reserved for the second recurrent episode or severe disease. There is no role for antimicrobial prophylaxis.
- The acute treatment of stable tachyarrhythmias in the noncardiothoracic postoperative patient is controversial. However, intravenous esmolol is more effective than diltiazem in conversion to sinus rhythm. There may be a role for amiodarone.
- Not all patients in Afib should be anticoagulated. Only patients with a CHADS2 score of 5 to 6 should be anticoagulated with warfarin if the risk a warfarin-associated complications is less than 10% per year.

Dynamic Wound Healing

6

Gina D. Jefferson

INTRODUCTION

The otolaryngologist–head and neck surgeon encounters wound healing problems on a regular basis. An in-depth knowledge of the wound healing process and potential complicating factors is therefore imperative. There are several factors that may adversely affect the normal wound healing process including trauma, malignancy, history of radiation at the site of the wound, advanced age, metabolic diseases such as diabetes mellitus, and autoimmune disorders, just to name a few. Moreover, wounds are classified according to various criteria. *Acute wounds* follow a time course of healing within 30 days. The wounds repair themselves in an orderly fashion following the normal healing pathway. A *chronic wound* fails to progress through the normal phases of wound healing and is incomplete because it is often disturbed by various factors that impede the process.

The evolution in understanding wound healing began with single author publications in the late 1800s. These early reports were largely anecdotal experiences shared by individual surgeons. Various antiseptic agents were described. There were even reports of large rotational skin flaps utilized to prevent contraction scar deformities. In 1903, Cushing described nerve anastomoses for facial paralysis. Oschner reported in a symposium on the importance of septic techniques in 1904. In 1909, the surgeon John Stage Davis of Johns Hopkins Hospital published the first of many papers regarding wound closure, grafts, and flaps. Horsley discussed techniques for suturing blood vessels and recurrent laryngeal nerves in 1912. In 1919, Depage emphasized principles gleaned from experiences of World War I including antisepsis, delayed closure, and debridement with specific considerations for wounds of special areas. In 1925, Ravdin was the first to publish about the morbidity, mortality, and wound complication rate of a major surgical service (1).

During the 1930s, several papers appeared presenting observations of studies regarding wounds, wound healing, repair, and sepsis. The time course and various aspects of wound healing were discussed, and the Halstedian principles on operative technique were re-emphasized. In 1938, Ives and Hirshfeld relayed the importance of bacteria from a patient's skin as a source of postoperative wound healing complications. During the late 1930s, the improvement in the course of wound healing was noted to occur with vitamin C and vitamin A supplementation (1).

During World War II, papers appeared espousing the use of penicillin to prophylax against surgical infection as well as papers regarding wound shock management, anesthesia, and wound pain. Jenkins described a new hemostatic agent, Gelfoam, in 1946 experimentally used for liver hemorrhage. Growth-promoting factors in tissues were reported in 1946 as well. In the 1950s, the role of nutrition was investigated with respect to wound healing. In 1956, Dunphy published regarding the role of vitamin C in collagen synthesis and the biochemical phases of wound healing. In 1964, factors influencing the incidence of wound infection led to the classification of wounds as clean, clean-contaminated, contaminated, and dirty. In the 1970s, Dunphy and others continued their research into the biochemistry of wound healing and the role and origin of various chemical mediators in the inflammatory process (1).

Recently, extensive research regarding adverse circumstances affecting wound healing has occurred. This research may lead to advanced treatment methodology directed at various phases of wound healing that targets specific substances or actually provide specific factors to improve the wound healing process.

THE NORMAL WOUND HEALING PROCESS

The biologic process of wound healing involves the sequential occurrence of four phases that are continuous and naturally overlap. One region of the wound may exhibit a different phase than the dominant phase occurring in another region of that same wound bed. These four phases of healing signal the introduction of specific cell types into the wound bed as depicted in Figure 6.1. Tissue injury incites the first phase, which is the coagulative and hemostatic phase of wound healing. The second inflammatory phase follows shortly thereafter. The body initiates wound repair with phase three, proliferation. Wound healing culminates with tissue remodeling. Importantly, all phases of wound healing depend upon the presence of various cytokines in order to accomplish the goal as briefly outlined in Table 6.1.

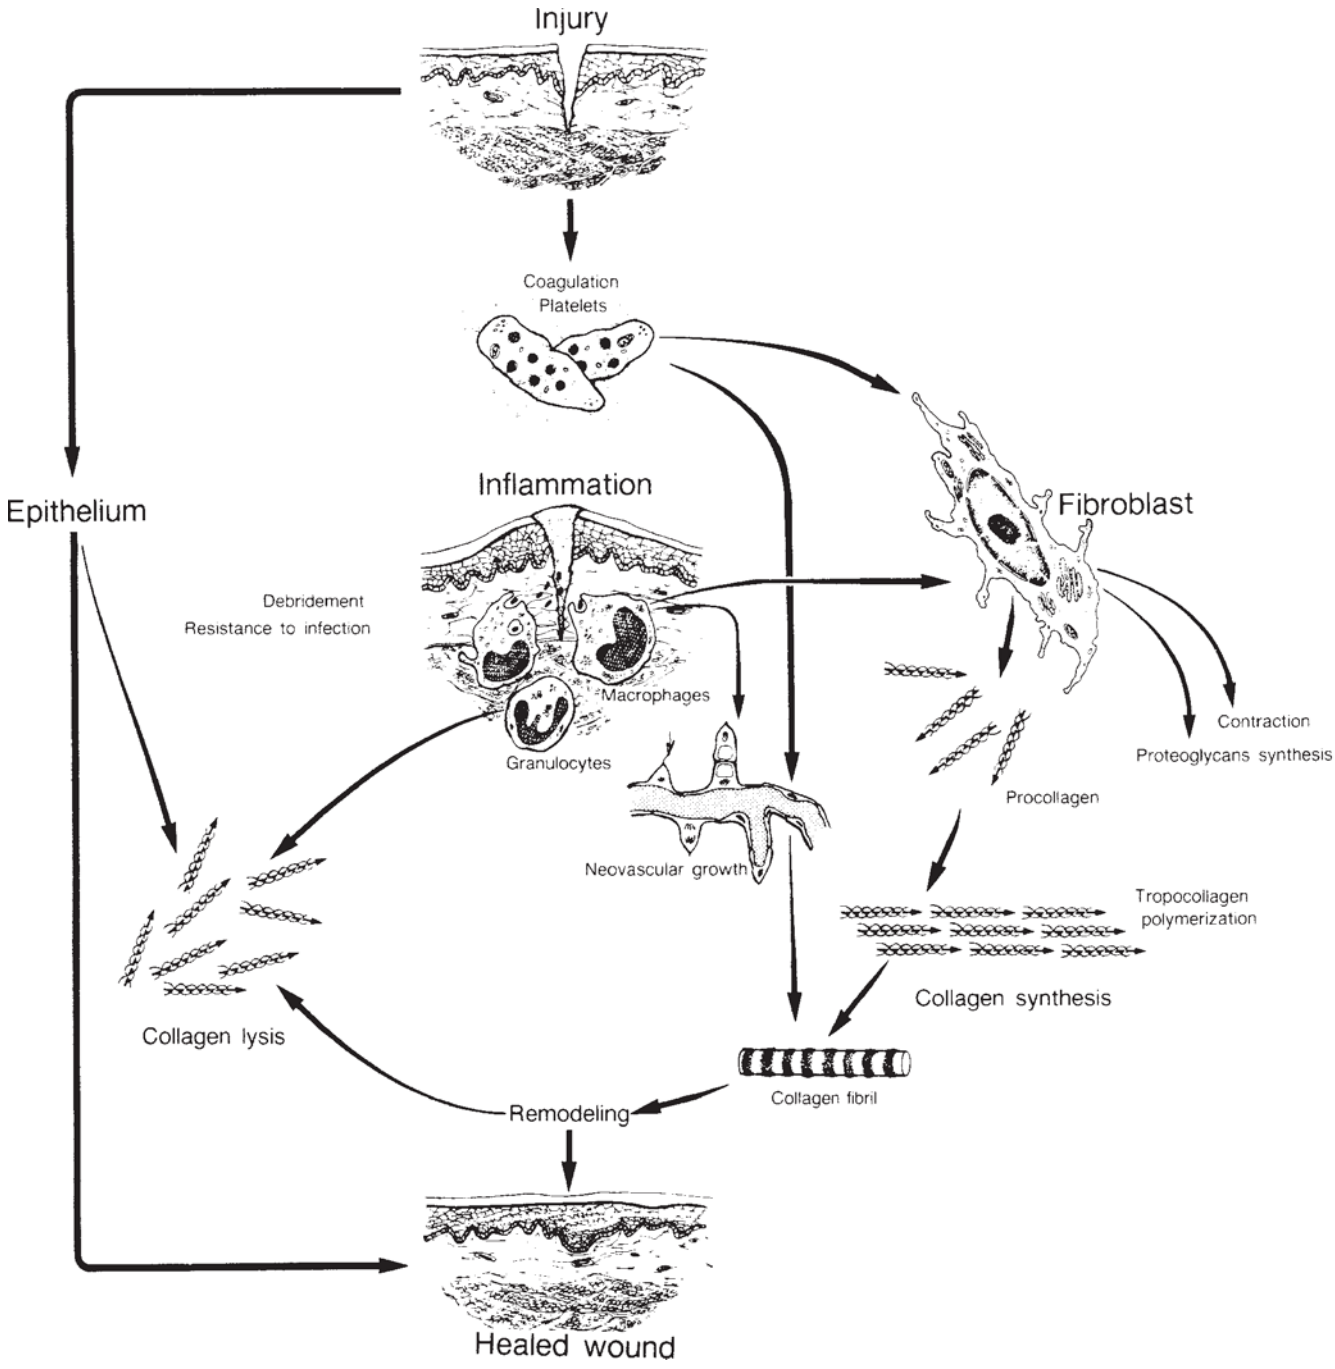

Figure 6.1 Brief depiction of the complexity of wound healing. (Modified and reprinted from Feinberg SE, Larson PE. Healing of traumatic injuries. In: Fonseca RJ, Walker RV, eds. *Oral and maxillofacial trauma*. Philadelphia, PA: WB Saunders, 1991, with permission.)

TABLE 6.1 CYTOKINES INVOLVED IN WOUND HEALING

Cytokine	Abbreviation	Source	Function
Human growth hormone	GH	Pituitary gland	Fibroblast proliferation; increases collagen content and tensile strength; anabolism; stimulates IGF-1
Epidermal growth factor	EGF	Platelets, bodily fluids (including saliva, urine, milk, and plasma)	Epithelial cell and fibroblast proliferation and migration; activates fibroblasts; angiogenic
Platelet-derived growth factor	PDGF	Platelets, macrophages, fibroblasts, endothelial cells, smooth muscle cells	Mitogenic for fibroblasts and smooth muscle cells; chemoattractant for neutrophils and macrophages; angiogenic
Fibroblast growth factors	FGF	Macrophages, brain, pituitary gland	Proliferation and migration of vascular endothelial cells; mitogenic and chemotactic for keratinocytes and fibroblasts
Transforming growth factors	TGF	Platelets, fibroblasts, neutrophils, macrophages, lymphocytes	Epithelial cell and fibroblast proliferation
Nerve growth factor	NGF	Schwann cell, muscle cells	Motoneurons, Schwann cells, muscle cells
Brain-derived neurotrophic factor	BDNF	Central nervous system, skeletal muscle, heart, lung	Support cranial and spinal motoneurons after axotomy
Ciliary neurotrophic factor	CNTF	Schwann cells	Promote survival and differentiation of neural and glial cells within the nervous system
Insulin-like growth factor 1	IGF-1	Fibroblasts, liver, plasma	Fibroblast proliferation, synthesis of proteoglycans and collagen
Tumor necrosis factor	TNF	Macrophages, mast cells, lymphocytes, other tissues and cells	Fibroblast proliferation
Interleukins	IL	Macrophages, lymphocytes, other tissues and cells	Fibroblast proliferation, neutrophil chemotaxis
Interferons	IFN	Fibroblasts, lymphocytes	Inhibition of fibroblast proliferation and collagen synthesis
Keratinocyte growth factors	KGF	Fibroblasts	Epithelial cell proliferation

Phase I: Coagulation and Hemostasis

The body's immediate response to tissue injury is to protect the vascular system and prevent exsanguination. In addition, this phase provides cells that serve as a matrix for other cells that eventually appear in the wound in the later stages of wound healing. Microvascular injury results in extravasation of blood into the wound. A reflex vasoconstriction occurs due to vascular smooth muscle contraction. This rapid reflex response can temporarily halt blood loss. After a few minutes, this environment becomes hypoxic and acidotic triggering vascular smooth muscle relaxation with the resumption of blood loss. Exsanguination is thwarted however by activation of the coagulation cascade.

The coagulation cascade (Fig. 6.2) assembles a platelet plug and clot via extrinsic and intrinsic pathways. Cellular injury extrinsically exposes a tissue factor lipoprotein ubiquitously present on cell membranes that leads to conversion of factor VII to an active protease and ultimately to the common pathway of the coagulation cascade. Likewise, the contact or intrinsic coagulation pathway creates a complex on exposed subendothelial collagen with factor XII, high molecular weight kininogen, and prekallikrein. These factors convert to active proteases after binding and together activate factor XI, which leads to the final common coagulation pathway via factor X activation. Factor X is activated by the calcium-dependent complex formed between factors VIII, IX, and X or directly by an activated factor VII. Finally, in the presence of calcium and phospholipid, factor V becomes activated, and in concert with activated factor X, prothrombin is converted to thrombin. Fibrinogen in turn is converted to fibrin, which ultimately cross-links and forms a stable platelet plug.

The platelet plug contains platelet-derived growth factor (PDGF), transforming growth factor-beta (TGF-β), epidermal growth factor (EGF), and insulin-like growth factor (IGF). These growth factors promote the activation and

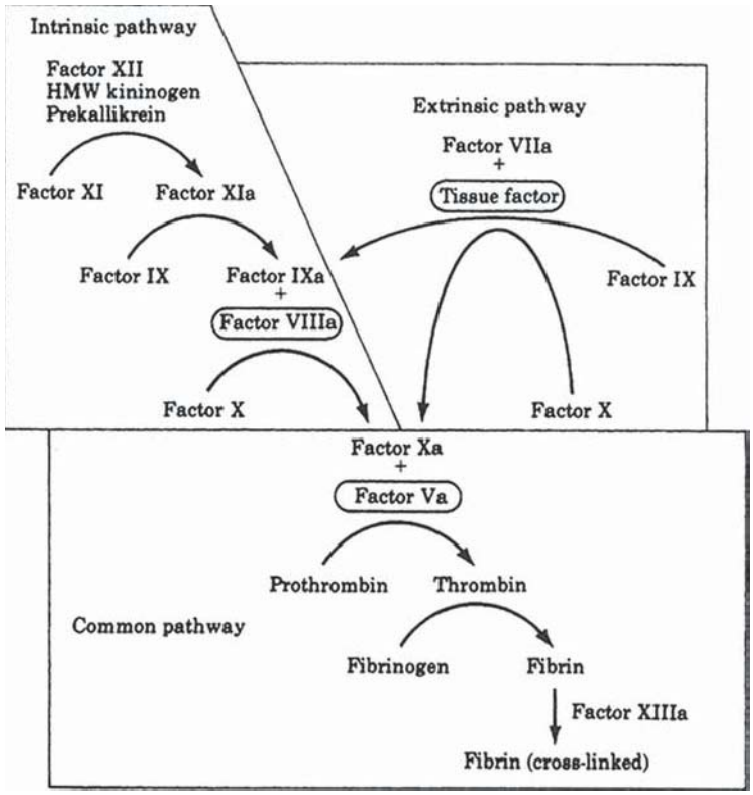

Figure 6.2 The coagulation cascade. (From Klingensmith ME. *Washington manual of surgery*, 5th ed. Lippincott Williams & Wilkins, 2005, with permission.)

chemotaxis of neutrophils, macrophages, endothelial cells, and fibroblasts. Platelets also contain vasoactive amines like serotonin that cause vasodilation and increased vascular permeability. Fluid extravasation occurs contributing the edema observed during the second phase of wound healing, the inflammatory phase (2,3).

Phase II: Inflammation

The inflammatory phase of wound healing functions to establish an immune barrier against invading bacteria. This phase is divided into an early phase and a late phase.

Early Inflammatory Phase

The early inflammatory phase of wound healing ensues during the late phase of coagulation during the first 24 to 36 hours after wounding occurs. This phase activates the complement cascade, which elaborates various chemoattractive factors such as C3a and C5a. These complement components synergistically act with local chemoattractive factors released from the activated platelets such as TGF-β to encourage neutrophil migration to the site of injury. Neutrophils are critical in performing phagocytosis to eliminate bacteria, foreign particles, and injured tissue components for the wound healing process to continue. Modification of surface adhesion molecules confers a sticky quality to neutrophils enabling the process of margination. Margination allows neutrophils to adhere to the endothelial cells of venules surrounding the wound bed. The endothelial cells secrete chemokines that activate a stronger adhesion system that is regulated by integrins. Through diapedesis, neutrophils migrate between endothelial cells to continue phagocytosis. Once neutrophils have completed their function of eliminating wound bacteria and foreign material, the products are extruded via apoptosis to the wound surface producing an exudate. This exudate is then further phagocytosed via macrophages (2,3).

Late Inflammatory Phase

The *late inflammatory phase* is heralded 48 to 72 hours of wounding with the appearance of macrophages. Macrophages originate as blood monocytes that undergo phenotypic changes upon arrival to the wound to become tissue macrophages. Macrophages have a longer lifespan than neutrophils and continue the function of phagocytosis of bacteria and foreign material within the wound bed. The macrophages are attracted to the wound by elaborated clotting factors, complement by-products, cytokines such as PDGF, TGF-β, leukotriene B_4, and platelet factor IV plus elastin and collagen breakdown products. Additional growth factors essential for the later phases of wound healing are released by tissue macrophages to influence the growth and behavior of fibroblasts, assist in wound revascularization, and produce factors to modulate proteins comprising the extracellular matrix (ECM) scaffold. These factors include transforming growth factor alpha (TGF-α), heparin-binding EGF, fibroblast growth factor (FGF),

and collagenase. Activated keratinocytes, fibroblasts, and endothelial cells also play a role (4).

The next cells to arrive at the site of injury are lymphocytes. After 72 hours, interleukin-1 (IL-1), complement components, and immunoglobulin G breakdown products all attract lymphocytes to the wound bed. Lymphocytes regulate collagenase, which is later needed for collagen remodeling and to assist in producing ECM components such as fibrin and fibronectin, as well as participate in their degradation (2,3).

Phase III: Proliferation

The proliferative phase of wound healing begins on day 3 after injury once hemostasis is achieved and an adequate immune response has occurred. This phase lasts for about 2 weeks. Fibroblasts originate from nearby connective tissue cells after growth factors released from tissue macrophages stimulate the mitosis and proliferation of fibroblasts for collagen synthesis. Fibroblasts migrate into the wound and synthesize a new ECM replacing the original fibrin–fibronectin matrix scaffold thereby providing the lattice for collagen synthesis. Granulation tissue represents this phase of wound healing. Importantly, unwounded dermis contains 80% type I collagen and 25% type III collagen. Early in wound healing, granulation tissue however contains 40% type III collagen rendering a lower tensile strength. Later in wound healing, this type III collagen is largely replaced by type I collagen; however, the maximum tensile strength achieved is 80% of the previously unwounded tissue (5).

Angiogenesis is also a component of proliferation. Angiogenesis is critical for the restoration of blood flow into a wound, for reoxygenation of the wound surface, and for the continuation of wound healing through all of its phases. The local tissue response to hypoxia is to increase the production of vascular endothelial growth factor (VEGF). In addition to VEGF, other angiogenic factors including FGF, PDGF, angiogenin, TGF-α, and TGF-β promote the proliferation and growth of endothelial cells. VEGF is secreted by macrophages and binds to endothelial cell receptor tyrosine kinases VEGFR1 and VEGFR2. Binding to these receptors initiates an intracellular signaling cascade to promote angiogenesis. The endothelial cells sprout capillary buds at the wound surface. Ultimately, these capillary buds form a network that join other networks sprouting from the wound bed (2,3).

Cellular migration is imperative for both angiogenesis and continued collagen formation and is dependent upon three processes: (a) protrusion at the cell front, (b) adhesion for the actin cytoskeleton to attach to the substratum, and (c) traction, which propels the trailing cytoplasm forward (2,3).

The cytoskeleton is anchored by cell–cell junctions and cell–ECM adhesions. The internal actin network reorganizes at the leading edge pushing the plasma membrane outward and forming a filopodia. The cyclic assembly and disassembly of actin filaments at the leading plasma membrane edge and behind the edge, respectively, permits unidirectional movement toward other capillary sprouting matrices and other forming ECM frameworks (2,3).

Integrins serve as the primary receptors for ECM proteins and are therefore necessary for cellular migration. Integrins also function in signal transduction and in the regulation and stimulation of cell migration. Increasing adhesion optimizes the rate of cellular migration; however, mobility declines with further attachment. After attachment to the underlying ECM, integrins signal a change in cellular morphology from an oval, spindle shape to an irregular, flat shape. This occurs initially at the leading migratory edge of the plasma membrane. Migration is fastest immediately after injury and slows to a steady state maintained during the remainder of the wound healing process. Traction is effected by contractile forces transmitted through the integrin–cytoskeletal connections. These connections allow the cell to pull its cytoplasm forward. It is the interaction between myosin and actin fibers that pull the cell body forward (2,3).

Epithelialization also begins shortly after injury. This starts from the wound periphery as a single layer of cells forming over the defect. There is a marked increase in epithelial cell mitotic activity around the wound edges, and cells migrate across the wound by attaching to the underlying provisional matrix. When advancing epithelial cells come into contact with one another, migration ceases and basement membranes begin to form.

Phase IV: Remodeling

New epithelium forms in this phase of wound healing along with final scar tissue formation. This phase may last as long as 1 or 2 years. Normal wound healing occurs with the establishment of a balance between degradation and synthesis. The collagen fibers increase their diameter, while hyaluronic acid and fibronectin are degraded. There are three important stimuli inciting the deposition of collagen: (a) high lactate content in the wound, (b) adequate oxygen levels, and (c) growth factors, namely, TGF-β. The collagen fibers initially appear in a haphazard orientation within the wound but eventually become more oriented and cross-linked. The oriented, cross-linked collagen may regain about 80% of the original strength of the wounded area in comparison to the unwounded condition. The synthesis and breakdown of collagen and ECM components occur continuously and simultaneously, equilibrating during the third week postinjury as the rate of collagen synthesis is maximal during the first 2 weeks after injury. Matrix metalloproteinases produced by neutrophils, macrophages, and fibroblasts at the wound site carry out the task of degradation.

Further wound organization occurs during the final stages of the remodeling phase via wound contraction that began during the proliferative phase. The wound's bed

TABLE 6.2 MAJOR COMPONENTS OF ECM

Component	Structure	Function
Collagen	Triple helical glycoprotein	Strength, support, and structure for all tissues and organs
Elastin	Stretchable hydrophobic protein	Expansion and contraction of tissues
Fibronectin	Large double-chain adhesive glycoprotein	Cell adhesion, locomotion, and differentiation
Laminin	Large cross-shaped adhesive glycoprotein	Cell and connective tissue adhesion, cell differentiation
Proteoglycans	Glycosaminoglycans covalently linked to a protein core	Regulation of connective tissue structure and permeability
Hyaluronic acid	Nonsulfated glycosaminoglycan	Fluid environment for cell movement and differentiation

of connective tissue shrinks thereby bringing the wound edges closer together. This is facilitated by fibroblast activity with the ECM scaffold. The main elements of the ECM are listed in Table 6.2. The ECM is comprised of proteoglycans, glycosaminoglycans, and mucoproteins made by fibroblasts. Fibronectin is produced by fibroblasts, endothelial cells, and platelets and forms the substrate for migration and ingrowth of cells initially and later serves as the template for collagen production and contributes to the debridement of wounds during this phase of remodeling. Apoptosis removes the fibroblasts and macrophages as the wound continues to heal, and the density of wound capillaries also declines resulting in a matured scar with a decreased number of cells and an increase in tensile strength.

All of the phases of wound healing are dependent upon various growth factors. These peptides promote cell growth, division, migration, and recruitment into injured tissue. Growth factors are synthesized by a variety of cells including platelets, macrophages, neutrophils, endothelial cells, and fibroblasts. The major growth factors that play a role in fibroblast activity are FGF, TGF-β, and PDGF. VEGF and cysteine-rich protein 61 (Cyr61) are the major proteins involved in regulating angiogenesis (2,3).

FGF exists in several different types, but acidic FGF-1, basic FGF-2, and keratinocyte growth factor are the dominant types contributing to wound healing. Dermal fibroblasts secrete FGF-1 and FGF-2, and their target of action are cells of mesodermal and neuroectodermal origin. They are responsible for the induction and acceleration of the proliferation of fibroblasts, vascular and capillary endothelial cells, keratinocytes, chondrocytes, and myoblasts (2).

TGF-β1 is synthesized by fibroblasts, platelets, macrophages, lymphocytes, and endothelial cells. It stimulates the migration of inflammatory cells and promotes the synthesis of ECM components collagen-1, glycosaminoglycans, and fibronectin. TGF-β1 also regulates the activity of growth factors FGF, PDGF, and EGF (2).

PDGF is stored in and secreted from the platelet alpha granules. PDGF is critical for the synthesis of connective tissue matrix and wound remodeling. It has a mitogenic effect on fibroblasts and stimulates the synthesis of glycosaminoglycans and proteoglycans (2).

VEGF is the principal polypeptide growth factor influencing endothelial cell migration and proliferation. The ordered activity of these two processes is integral for continued wound healing proliferation. VEGF is a member of the PDGF family and is essential for angiogenesis in health and pathophysiology. Nitric oxide enhances VEGF synthesis in vascular smooth muscle cells. Nitric oxide coupled with modified low-density lipoprotein augments VEGF production in macrophages (2).

Cyr61 is a heparin-binding, ECM-associated protein and participates in the induction of angiogenesis. It mediates cell adhesion and induces adhesive signaling, stimulating cell migration, enhancing cell proliferation, and promoting cell survival in both fibroblasts and endothelial cells. Cyr61 regulates the expression of genes involved in angiogenesis, inflammation, matrix remodeling, and cell-matrix adhesions (2).

FACTORS AFFECTING WOUND HEALING

There are a host of pathophysiologic and metabolic factors that can adversely affect the process of wound healing (Table 6.3). These factors include local edema, ischemia, tissue hypoxia, infection, necrosis, and growth factor imbalance, as well as systemic causes such as metabolic disease like diabetes, nutritional status, and other preexisting illness. In addition, external factors such as previous exposure to radiation can significantly and negatively impact the wound healing process.

Local edema increases wound tension leading to an increase in tissue pressure. This scenario reduces microperfusion within the wound and the availability of oxygen to the wound. Oxygen is essential to the wound healing process. Oxygen prevents wounds from infection; stimulates angiogenesis; increases keratinocyte differentiation, migration, and re-epithelialization; enhances fibroblast proliferation and collagen synthesis; and promotes wound contraction. Oxygen levels, namely, superoxide, are also critically important for the neutrophil function of oxidative phagocytosis of pathogens within a wound during the inflammatory phase of wound healing. Temporary hypoxia after injury stimulates the wound healing process; however, chronic hypoxia delays wound healing (6,7).

Infections also impede the wound healing process. After wounding, microorganisms that usually reside on the skin surface have direct access to the underlying tissue. Wound

TABLE 6.3 FACTORS THAT IMPEDE WOUND HEALING

Disease States	Local Factors
Hereditary	Ischemia
Coagulation disorders	Infection
Ehlers-Danlos/Marfan's	Tissue trauma
Prolidase deficiency	Retained foreign body
Werner syndrome	Desiccation
Vascular disorders	Medications
Congestive heart failure	Glucocorticoids
Atherosclerosis	Anticoagulants
Hypertension	Antineoplastic agents
Vasculitis	Colchicine
Venous stasis	Penicillamine
Lymphedema	Vitamin E
Metabolic	Salicylates (high dose)
Chronic renal failure	Nonsteroidals (high dose)
Diabetes mellitus	Zinc sulfate (high dose)
Malnutrition	Vitamin A (high dose)
Cushing syndrome	
Hyperthyroidism	
Immunologic deficiency states	
Others	
Chronic pulmonary disease	
Liver failure	
Malignancy	

contamination refers to the presence of nonreplicating organisms on a wound surface, while colonization indicates the presence of replicating microorganisms on the wound without causing tissue damage. Invasive infection denotes the presence of replicating microorganisms within a wound that results in host injury. When the inflammatory phase of wound healing is prolonged or ineffective at removing debris and bacteria, prolonged elevation of proinflammatory cytokines such as IL-1 and TNF-α further prolongs inflammation. Increased duration of inflammation leads to augmented levels of matrix metalloproteases (MMPs) that serve to degrade the ECM under production during the proliferative phase. This excess level of proteases also contributes to the degradation of growth factors, and these growth factors are necessary for the process of wound healing (6,7).

In addition, bacteria in chronic infected wounds have the opportunity to form communities of aggregated microorganisms maintained within an extracellular polysaccharide matrix they secrete. The biofilm-protected environment renders the contained organisms resistant to conventional antibiotic therapy. *Pseudomonas* and *Staphylococcus* species may utilize a biofilm environment to shield themselves from the phagocytic activity of invading neutrophils and hence the failure of antibiotics to cure chronic wounds (6).

The systemic factor of older age, that is, patients over the age of 60, also is known to adversely affect wound healing. Healthy older patients experience a temporal delay in wound healing but not an actual quality defect of the healing process. Delayed wound healing in the aged is associated with an alteration of every phase of the wound healing process. Hemostasis is affected by enhanced platelet aggregation. Inflammation is affected by an increase in number of secreted inflammatory mediators, delayed infiltration of macrophages and lymphocytes to the wound site, and impaired macrophage function. The proliferative phase is altered by a decreased amount of secreted growth factors, delayed re-epithelialization and angiogenesis. Remodeling is adversely affected by decreased collagen deposition, a reduction in collagen turnover, and overall decreased wound strength (6).

Studies indicate that estrogen can improve the age-related impairment in healing in both men and women and that aged males experience a delay in the wound healing process in comparison to aged females. Female estrogens estrone and 17β-estradiol regulate a variety of genes associated with regeneration, matrix production, protease inhibition, epidermal function, and the genes primarily associated with inflammation. On the other hand, male androgens testosterone and 5α-dihydrotestosterone and their steroid precursor dehydroepiandrosterone affect wound healing in a negative manner (6).

Many diseases, for example, cardiovascular disease and cancer, are associated with stress. Stress results in the deregulation of the immune system. This is mediated primarily by the hypothalamic–pituitary–adrenal system and the sympathetic–adrenal–medullary axis. Many studies also suggest that psychological stress also results in delayed wound healing. Stress upregulates glucocorticoids and thereby reduces the levels of proinflammatory cytokines IL-1 β, IL-6, and TNF-α at the wound site. Stress also results in decreased amounts of the chemoattractants IL-1α and IL-8 at the wound sites, which are both necessary during this inflammatory phase of wound healing. Glucocorticoids further adversely act on wound healing by suppressing differentiation and proliferation, gene transcription, and reducing the expression of cell adhesion molecules involved in immune cell trafficking (6).

Diabetic patients are documented to have impairment in the healing process of acute wounds. Diabetic wounds are accompanied by hypoxia. As discussed previously in this chapter, hypoxia can amplify and prolong the early inflammatory response resulting in an increased amount of oxygen radicals within the wound. Hyperglycemia can also add to the oxidative wound stress when the production of reactive oxygen species exceeds the antioxidant capacity. In addition, high levels of MMPs increase tissue destruction and inhibit normal repair processes. Diabetic wounds display dysregulated T-cell immunity; defective leukocyte chemotaxis, phagocytosis, and bactericidal capacity; and dysfunctional fibroblast and epidermal cell activity. This results in inadequate bacterial clearance and delayed wound healing. There is also impairment of angiogenesis in the diabetic wound. There is a defect in epithelial cell

mobilization and homing and a decreased level of VEGF, the primary angiogenic factor, in the diabetic wound (6,8).

The neuropathy that occurs in diabetic individuals also affects wound healing. Neuropeptides such as nerve growth factor, substance P, and calcitonin gene-related peptide normally promote cell chemotaxis, induce growth factor production, and stimulate the proliferation of cells. These factors are decreased in diabetic patients with peripheral neuropathy. In addition, sensory nerves play a role in modulating immune defense mechanisms and denervated skin experiences a reduction of leukocyte infiltration (6,8).

Some commonly used medications such as nonsteroidal anti-inflammatory drugs (NSAIDs) and glucocorticoids may contribute to impaired wound healing. These agents interfere with clot formation, platelet function, the inflammatory phase of wound healing, as well as negatively impact the proliferative phase of wound healing. NSAIDs are widely used for the treatment of inflammation and arthritis as well as for pain management. Low-dose aspirin is also commonly prescribed for its antiplatelet properties for cardiovascular health but not as an anti-inflammatory agent. There is limited data to suggest a negative impact on wound healing with the short-term use of NSAIDs; however, the long-term use of NSAIDs and their negative effect on wound healing is not clearly defined. Some animal models have shown an antiproliferative effect on wound healing, which results in decreased numbers of fibroblasts, weakened wound breaking strength, decreased wound contractility, delayed epithelialization, and impaired angiogenesis. Glucocorticoids cause global anti-inflammatory effects and suppression of cellular wound responses. There is suppression of fibroblast proliferation and collagen synthesis. Wounds heal with incomplete granulation tissue and reduced wound contraction. There is an inhibition of the necessary transcriptional factor hypoxia inducible factor-1 (HIF-1). Glucocorticoids also predispose to wound infection, and its negative impact on wound healing was discussed previously (6).

Obese patients often experience wound complications including skin wound infection, dehiscence, hematoma and seroma formation, pressure ulcers, and venous ulcers. An increased rate of surgical site infection often occurs in obese individuals likely due to a relative hypoperfusion and ischemia in the subcutaneous adipose tissue. Surgical wounds in the obese display increased tension at the wound edges, and this can contribute to wound dehiscence. Wound tension also increases tissue pressure, which in turn reduces the microcirculation and hence oxygen levels of the wound. In addition, obese patients have excessive skin folds that often harbor microorganisms that thrive in moist environments and can contribute to infection and tissue breakdown. The friction generated by skin on skin contact also leads to ulceration. Obesity is also linked to stress, anxiety, and depression, conditions that can impair the host immune response (6).

Alcohol exposure affects wound healing as well, namely, by increasing host susceptibility to infection. Short-term alcohol exposure suppresses proinflammatory cytokine release in response to an inflammatory challenge. The higher incidence of postinjury infection correlates with decreased neutrophil recruitment and phagocytic function in the acute alcohol exposed state. The most significant impairment associated with alcohol exposure is wound angiogenesis. There is a decreased expression of VEGF receptors and a reduced nuclear expression of HIF-1α in endothelial cells that reduces wound angiogenesis by up to 60% after a single alcohol exposure. Connective tissue restoration is also negatively impacted by acute alcohol exposure due to decreased levels of collagen production and an overall increase in wound proteases. Chronic alcohol exposure also negatively affects wound healing; however, the exact mechanisms remain unclear (6).

Likewise, smoking inhibits wound healing. There is a delay in wound healing and a predisposition to the development of postoperative infection, wound dehiscence and rupture, anastomotic leakage, wound and flap necrosis, epidermolysis, and decreased tensile strength of the wound. Cosmetic outcomes are also worse in patients who continue smoking in the perioperative period. Nicotine acts as a vasoconstrictor thereby interfering with wound oxygen supply by inducing tissue ischemia. Nicotine also stimulates sympathetic nervous activity that results in the release of epinephrine into the circulation that also serves as a vasoconstrictor in the peripheral circulation and decreases tissue blood perfusion. Nicotine increases blood viscosity caused by decreased fibrinolytic activity and augmented platelet adhesiveness. Cigarette smoke carbon monoxide binds to hemoglobin with an affinity 200 times greater than that of oxygen resulting in a decreased fraction of oxygenated hemoglobin in the circulation (6,9).

Smoking adversely affects the inflammatory phase by impairing neutrophil migration and reducing the neutrophil bactericidal activity. Lymphocyte function, cytotoxicity of natural killer cells, and the production of IL-1 are all depressed, and macrophage ability to sense gram-negative bacteria is also compromised. The proliferative phase is impaired by a decreased fibroblast migration and proliferation, reduced wound contractility, hindered epithelial regeneration, decreased ECM production, and established unfavorable wound protease balance. Smoking cessation improves repair and reduces the incidence of wound infection even within 7 days of surgery (6,9).

Protein is one of the most important nutrient factors affecting wound healing. A deficiency of protein can impair capillary formation, fibroblast proliferation, proteoglycan synthesis, collagen synthesis, and wound remodeling (3). Protein deficits also negatively impact the immune system evidenced by decreased neutrophil phagocytosis and increased susceptibility to wound infection. Collagen is the major protein component of connective tissue and is primarily comprised of glycine, proline, and hydroxyproline. Collagen synthesis depends upon the hydroxylation of lysine and proline. Ferrous iron and vitamin C are necessary cofactors for this hydroxylation. Arginine also exerts many

effects on the body, including the modulation of immunity, wound healing, hormone secretion, vascular tonicity, and endothelial function. Arginine also serves as a precursor to proline. Deficiency of arginine can therefore lead to inadequate collagen deposition, angiogenesis, and impaired wound contractility. Insufficient levels of glutamine result in an inadequate inflammatory immune response in the early phases of wound healing. It is hypothesized that omega-3 fatty acids are involved in the proinflammatory cytokine production, cell metabolism, gene expression, and angiogenesis at the site of a wound and that deficits of the fatty acid may predispose to host wound infection (6,10,11).

Vitamin C deficiency is well known to result in impaired collagen synthesis and fibroblast proliferation, decreased angiogenesis, and increased capillary fragility. There is also an increased susceptibility to wound infection. Vitamin A deficiency impedes antioxidant activity, fibroblast proliferation, cellular differentiation and proliferation, collagen and hyaluronate synthesis, and MMP-mediated ECM degradation. Vitamin A increases the inflammatory response in wounds through enhanced lysosomal membrane lability, increased macrophage influx, and activation and stimulation of collagen synthesis (6). Inadequate levels of vitamin E also impede antioxidant activity within a wound. The wound also suffers instability of cellular membrane integrity and may lead to excessive scar formation. Zinc deficiency significantly impairs wound healing as this micronutrient is necessary for RNA and DNA polymerase activity, DNA synthesis, protein synthesis, and cellular proliferation (10). The micronutrient iron is required for the hydroxylation of proline and lysine, and severe iron deficiency results in decreased collagen production. A study by Heyman et al. illustrates the importance of vitamins and micronutrients on wound healing. The study demonstrated that a high-energy, protein-enriched supplement containing arginine, vitamin C, vitamin E, and zinc improves the overall healing of chronic pressure ulcers (6,10,11).

It is also incumbent upon the surgeon to preoperatively inquire about patient use of herbal supplements. Dong quai, also known as female ginseng, is notable for coumadin-like properties and interference with the clotting mechanism. Echinacea displays immunosuppressive properties (6).

Similarly, the head and neck surgeon must also respect the previously radiated neck in this era where definitive chemoradiation therapy is commonly employed for our head and neck cancer patients whom may eventually require a salvage surgical procedure. Ionizing radiation results in endothelial cell injury causing endarteritis. This in turn leads to wound atrophy, fibrosis, and delayed tissue repair. Injury of a previously irradiated wound does *not* lead to angiogenesis. Radiotherapy alters the balance between the wound healing promotion local mediators and those mediators that act to inhibit the process. Radiation is employed to cure various cancers due to its greatest effect on cells in the G2 through M phases of the cell cycle. That is, cell populations that are rapidly dividing are those cells most sensitive to the effects of radiation. Such cells include fibroblasts and keratinocytes. Therefore, wounds occurring in a previously irradiated site display impaired formation of granulation tissue as well as dysfunctional epithelialization (12).

DERANGEMENTS OF WOUND HEALING

A spectrum of scar formation ranging from normal scar formation to normotrophic, hypertrophic, and keloid scar formation warrants consideration by the otolaryngologic surgeon as well. Abnormal scar formation can lead to both functional and cosmetic problems such as limitation of mobility and aesthetic disfigurement causing psychosocial repercussions.

There remains controversy regarding the distinction among the various scar types histologic description and etiology largely due to nonstandardization of methods employed to determine histologic characterization. Normotrophic scars are often described with characteristics similar to hypertrophic scars except the height of scar elevation above the normal skin surface is less than 2 mm. Hypertrophic scars are severe excessive scars that are frequently described as histologically containing an abundance of collagenous scar tissue and hypercellularity consisting of mainly myofibroblasts. The scar is phenotypically elevated greater than 2 mm above the normal skin surface. The exact etiology is unknown; however, it is theorized that failure of apoptosis at the conclusion of the proliferative phase of wound healing to eliminate the myofibroblasts leads to this excessive scar formation of a hypertrophic scar (13,14). Keloids are benign skin tumors that occur in patients with genetic predisposition and are thought to arise in part to upregulation of TGF-β. Keloid scars grow outside the confines of the original wound bed in contrast to hypertrophic scars that present as an elevation of the scar maintained within the confines of the original wound bed.

Several reports have suggested histologic differences between scar types with respect to collagen orientation and thickness of the collagen bundles. However, many of these reports contradict each other, and thus, the histopathologic characteristic differences remain unclear. Further investigation is warranted as treatment efficacy is dependent upon elucidation of etiology and behavioral characteristics of these deranged scars (13,15).

METHODS TO IMPROVE WOUND HEALING

Hyperbaric oxygen (HBO) treatment is a therapy employed since the 1960s adjunctively in the management of mandibular osteoradionecrosis (ORN). ORN was theorized by Marx to result from tissue hypoxia, hypocellularity, and hypovascularity. HBO is utilized to increase the blood–tissue oxygen gradient. This in turn enhances the diffusion of oxygen into hypoxic tissue. An increase in oxygen supply stimulates

fibroblast proliferation, angiogenesis, and collagen formation. Increased oxygen tension is also bactericidal and bacteriostatic (16–18). Recently new protocols have emerged for the prevention and treatment of ORN, challenging the utility of HBO therapy. Also employed during the early stages of ORN, pentoxifylline, for example, is one of a few medications recently espoused as efficacious. The mechanism of action of pentoxifylline is to decrease the viscosity of blood and hence improve the peripheral circulation and oxygen supply to the affected area. This too is the ultimate effect of HBO therapy. There remains a role for HBO therapy in the treatment of early stage ORN, whereas this conservative medical treatment modality will not successfully treat patients with pathologic fracture, fistula formation, or chronic infection, which ultimately requires reconstruction, such as free tissue transfer, after composite resection (18,19).

The local wound environment proton gradient, or pH, changes throughout the phases of wound healing. Each phase is dependent upon a particular pH range as enzyme activity fluctuates due to change in pH. The ability to alter wound pH may prove a promising, inexpensive strategy for improving chronic wound healing. For example, the application of a biodegradable polymer that releases certain growth factors, such as FGF, where the release occurs in a pH dependent fashion may optimize the activity of FGF during the inflammatory and proliferative phases of wound healing. In addition, pH changes affect bacterial colonization. For instance, elevated pH encourages *Candida albicans* infection of the wound. The ability to alter the pH of the wound environment can lessen the incidence of candidiasis of chronic wounds (20,21).

Another promising wound healing therapeutic are antimicrobial peptides. Antimicrobial peptides may influence the proliferation and migration of keratinocytes as well as their cytokine and chemokine production. Likewise, the proliferative phase, in particular the re-epithelialization process, is potentially modified by stimulation of such peptides (20).

Also during the proliferative phase, the mammalian target of rapamycin, mTOR, plays a role in re-epithelialization. mTOR is an FK506-binding protein/rapamycin-associated protein kinase that is upregulated in wounded stratified epithelia. Proliferation and protein synthesis of keratinocytes increase as a result. When this process is unchecked or overactive, hypertrophic scarring or keloid scarring may occur. This is evidenced by reports of increased levels of mTOR in keloid scars. Therefore, the ability to locally inhibit mTOR via agents such as rapamycin may help prevent hypertrophic or keloid scarring in the future (20).

A novel topical wound healing aid known as calreticulin induces proliferation of keratinocytes, fibroblasts, and endothelial cells in vitro. These cells play a role in all phases of wound healing. In a porcine model, calreticulin has enhanced macrophage recruitment to the wound bed, improved granulation, and stimulated granulation and re-epithelialization (20).

Other potential wound healing adjuncts include gene transfer, the use of stem cells, and modulation of the peripheral nervous system. Gene transfer via transfected allogenic keratinocyte cell suspensions, for example, could potentially transplant growth factors like epidermal growth factor into a wound bed to enhance the proliferative phase of wound healing (20). A recent study conducted at Stanford University demonstrated regeneration capability of mice skull defects via chemical control of FGF-2 exposure to adipose stem cells. By genetically fusing a protein of interest, FGF-2, to a destabilizing protein domain, the construct permits spatial and temporal control of signaling factor. FGF-2 has previously proven to increase the proliferation of mouse adipose stem cells while maintaining the potential for differentiation. This study thereby illustrates the ability for chemical control of important protein factors in tissue engineering and potentially wound healing (21,22).

Similarly, there exists a newly discovered network between the nervous system and the immune system. Various neuropeptides and cytokines cross talk. For example, substance P acts as an injury-inducible factor early in the wound healing process. Perhaps substance P and other neuropeptides have a potential application in improving the wound healing process (20,21).

These are just a few examples of the ongoing research regarding the molecular mechanisms vital to the wound healing process that may result in improvement of the wound healing process in the future.

HIGHLIGHTS

- Wound healing is a complex process accomplished by four phases that naturally overlap including the coagulative and hemostatic phase, the inflammatory phase, the proliferative phase, and the remodeling phase.
- A variety of cytokines and growth factors play a vital role in the various phases of wound healing including PDGF, TGF-β, TGF-α, EDGF, VEGF, FGF-1, and FGF-2.
- Several adverse conditions may contribute to aberrant wound healing including local edema, tissue hypoxia, infection, metabolic diseases such as diabetes mellitus, malnutrition, nutrition medications, and advanced age to name a few.
- Collagen is a major component of ECM that is initially deposited in a wound primarily as type III, which is largely replaced by type I collagen as wound healing progresses and an equilibrium is established between collagen synthesis and breakdown during the remodeling phase.
- The maximum wound tensile strength attained does not exceed 80% of the previously unwounded tissue strength.
- Ongoing research continues regarding targeted modification of the wound healing process such as inhibition of mTOR, the mammalian target of rapamycin, to prophylax against the formation of hypertrophic or keloid scars.

7 Understanding Data and Interpreting the Literature

Richard M. Rosenfeld

"It is a capital mistake to theorize before one has data," observed Sherlock Holmes. Physicians are rarely guilty of this offense, because they are inundated with data from clinical observations, journal articles, professional meetings, and governmental agencies. Unfortunately, the theories that result often have little relevance to the data that produced them. This is not unexpected, because physicians rarely devote the same efforts to mastering data that they devote to mastering clinical skills. As a partial remedy, this chapter offers a principle-centered approach to data analysis with emphasis on interpreting the medical literature (1,2).

Nearly all data relevant to clinical care comes from articles in peer-reviewed medical journals, whose content is generally assessed using principles that mirror those in this chapter (3).Unfortunately, the process of editorial peer review is largely untested and its effects are uncertain. Manuscript assessment, like even the most sophisticated diagnostic tests, has a certain sensitivity and specificity; worthy articles may be unappreciated (and unpublished) or worthless ones may pass undetected to the printing press. Peer reviewers may be biased, unqualified, or possess widely discrepant opinions about a study. The bottom line? Caveat lector: beware of what you read even in excellent medical journals.

Of more concern to clinicians than the inadequacies of peer review, however, is that the medical literature generally serves science rather than medical practice. Peer-reviewed publications facilitate communication from scientist to scientist, not necessarily from scientist to clinician. Most published studies are nondefinitive tests of hypotheses and innovations, only a very small percentage of which may warrant routine clinical application. Whereas the science may be sound, the idea has not progressed beyond the laboratory or preliminary field studies. Definitive studies constituting true scientist to clinician communication are rare in medical journals, and must be identified by critical appraisal.

Clinicians can use the medical literature to support clinical decisions in two complimentary ways: regular surveillance (or browsing) and problem-oriented searches. While the latter mode is more effective for learning, both are necessary for continuing clinical competence. Both methods require appreciating the purposes of the medical literature and understanding of the strengths and weaknesses of various study designs for providing valid and clinically applicable information.

HOW TO IDENTIFY ARTICLES WORTH READING

Articles worthy of in-depth analysis have enticing titles and abstracts, which espouse innovative, controversial, or clinically relevant ideas. Reading the abstract alone, however, is a poor substitute for perusing the entire article. Whereas abstracts in otolaryngology journals generally do convey information about study design, sample size, and the source of the data, they infrequently describe adverse events, study limitations, and dropouts or losses (4). Abstracts may also report selective, incomplete, or inaccurate data leading to biased conclusions. Abstracts are a starting point for analysis, not the finish line.

Worthy articles appear as original research in the main section of a peer-reviewed journal. Methods and results sections, which represent the heart and soul of the article, should be appropriately detailed and lengthy. Statistical reporting includes confidence limits and measures of clinical benefit (5). Enough details should be provided for you to reproduce the study on your own, if desired, with a reasonable chance of obtaining the same results. A quick review of the paper in general should disclose many of the signs of grandeur in Table 7.1.

TABLE 7.1 SIGNS OF GRANDEUR AND DECADENCE IN JOURNAL ARTICLES

Section	Signs of Grandeur	Signs of Decadence
Abstract	Structured summary of goals, methods, results, and significance	Unstructured qualitative overview of study; contains more wish than reality
Introduction	Clear, concise, and logical; ends with study rationale or purpose	Rambling, verbose literature review; no critical argument or hypothesis
Methods	Specific enough for the reader to reproduce the study and understand how quantitative results were generated	Vague or incomplete description of subjects, sampling, outcome criteria; no mention of statistical analysis
Results	Logical blend of narrative and numbers, including 95% CIs, with supporting tables and figures	Difficult to read, with overuse or underuse of statistical tests; emphasis on P-values, not clinical importance
Discussion	Puts main results in context; reviews supporting and conflicting literature; discusses strengths and weaknesses	Full of fantasy and speculation; rambling and biased literature review; does not acknowledge weaknesses
References	Demonstrates clearly that work of others has been systematically considered; emphasizes original research from peer-reviewed journals	Key articles are conspicuously absent; excessively brief; emphasizes review articles, book chapters, and lower-quality journals

Articles unworthy of in-depth analysis may have enticing titles and abstracts, but have no ability to support the lofty claims and conclusions therein. The article may appear in a non–peer-reviewed (throwaway) journal or in an industry-funded supplement to the main section (which generally implies lower quality). Signs of decadence (Table 7.1) are readily apparent when perusing the article's main sections. The methods and results sections are vague and sparse, overshadowed by a verbose discussion section with unsupported opinions and creative misinterpretations. Don't waste any time analyzing an unworthy article unless the premise is so novel and important that it overshadows the obvious weaknesses.

FIVE BASIC QUESTIONS FOR INTERPRETING DATA

As expert clinicians consider something abnormal until they examine it and prove otherwise, a connoisseur of medical evidence considers a data set or a journal article to be laden with flaws, distortions, and omissions until proven to the contrary. The five basic questions in Table 7.2 are the key to this analytic process. Each question is discussed below using established principles of data analysis and literature interpretation (1).

Question 1: How Was the Study Performed

Study Design

Medical data arise from a research study, defined as an "organized quest for new knowledge, based on curiosity or perceived needs" (6). Validity of the data is determined in large part by the study design (specific procedures and methods) used by the investigators to produce their data. The study design must fit the research question. Despite the befuddling array of study designs espoused in the epidemiologic literature, the savvy data analyst need only address a few basic considerations (Table 7.3). These relate to (a) how the data were gathered, (b) what degree of control the investigator had over study conditions, (c) whether a control or comparison group was used, and (d) what direction of inquiry was followed.

Data collected specifically for research (Table 7.3) are likely to be unbiased—they reflect the true value of the attribute being measured. In contrast, data collected during routine clinical care will vary in quality. *Experimental* studies, such as randomized trials, are likely to produce high-quality data because they are performed under carefully controlled conditions. In *observational* studies, however, the investigator is simply a bystander who records the natural course of health events during clinical care. Regardless of data quality bias may be introduced at any stage of the research process, which includes reviewing literature, defining baseline states, performing interventions, measuring outcomes, analyzing data, and publishing results (7).

The presence or absence of a *control group* has a profound influence on data interpretation. An uncontrolled study—no matter how elegant—is purely descriptive (2). Case series, which appear frequently in the otolaryngology literature, *cannot* assess efficacy or effectiveness, but they *can* convey feasibility, experience, technical details of an intervention, and predictive factors associated with good outcomes or adverse events (8). The best case series use a consecutive sample of patients, adjust for interfering

TABLE 7.2 FIVE BASIC QUESTIONS FOR INTERPRETING MEDICAL DATA

Question	Why It Is Important	Underlying Principles
1. What type of study produced the data?	Study design has a profound impact on interpretation; scrutinize the data collection, degree of investigator control, use of control groups, and direction of inquiry	Bias, research design, placebo effect, control groups, causality
2. What are the results?	Results should be summarized with appropriate descriptive statistics; positive results must be qualified by the chance of being wrong, and negative results by the chance of having missed a true difference	Measurement scale, association, *P* value, power, effect size, clinical importance
3. Are the results valid within the study?	Proper statistical analysis and data collection ensures valid results for the subjects studied; measurements must be accurate and reproducible	Internal validity, accuracy, statistical tests
4. Are the results valid outside the study?	Results can be generalized when the sampling method is sound, subjects are representative of the target population, and sample size is large enough for adequate precision	External validity, sampling, CIs, precision
5. Are the results strong and consistent?	A single study is rarely definitive; results must be viewed relative to their plausibility, consistency with past efforts, and by the strength of the study methodology	Research integration, level of evidence, systematic review

TABLE 7.3 EFFECT OF STUDY DESIGN ON DATA INTERPRETATION

Aspect of Study Design	Effect on Data Interpretation
How were the data originally collected?	
Specifically for research	Interpretation is facilitated by quality data collected according to an a priori protocol
During routine clinical care	Interpretation is limited by the consistency, accuracy, availability, and completeness of the source records
Database or data registry	Interpretation is limited by representativeness of the sample and the quality and completeness of data fields
Is the study experimental or observational?	
Experimental study with conditions under direct control of the investigator	Low potential for systematic error (bias); bias can be reduced further by randomization and masking (blinding)
Observational study without intervention other than to record, classify, analyze	High potential for bias in sample selection, treatment assignment, measurement of exposures, and outcomes
Is there a comparison or control group?	
Comparative or controlled study with two or more groups	Permits analytic statements concerning efficacy, effectiveness, and association
No comparison group present	Permits descriptive statements only, because of improvements from natural history and placebo effect
What is the direction of study inquiry?	
Subjects identified prior to an outcome or disease; future events recorded	Prospective design measures incidence (new events) and causality (if comparison group included)
Subjects identified after an outcome or disease; past histories are examined	Retrospective design measures prevalence (existing events) and causality (if comparison group included)
Subjects are identified at a single time point, regardless of outcome or disease	Cross-sectional design measures prevalence (existing events) and association (if comparison group included)

TABLE 7.4 EXPLANATIONS FOR FAVORABLE OUTCOMES IN TREATMENT STUDIES

Explanation	Definition	Solution
Bias	Systematic variation of measurements from their true values; may be intentional or unintentional	Accurate, protocol-driven data collection
Chance	Random variation without apparent relation to other measurements or variables (e.g., getting lucky)	Control or comparison group
Natural history	Course of a disease from onset to resolution; may include relapse, remission, and spontaneous recovery	Control or comparison group
Regression to the mean	Symptom improvement independent of therapy, as sick patients return to a mean level after seeking care	Control or comparison group
Placebo effect	Beneficial effect caused by the expectation that the regimen will have an effect (e.g., power of suggestion)	Control or comparison group with placebo
Halo effect	Beneficial effect caused by the manner, attention, and caring of a provider during a medical encounter	Control or comparison group treated similarly
Confounding	Distortion of an effect by other prognostic factors or variables for which adjustments have not been made	Randomization or multivariate analysis
Allocation (susceptibility) bias	Beneficial effect caused by allocating subjects with less severe disease or better prognosis to treatment group	Randomization or comorbidity analysis
Ascertainment (detection) bias	Favoring the treatment group during outcome analysis (e.g., rounding up for treated subjects, down for controls)	Masked (blinded) outcome assessment

variables, plan in advance for systematic data collection, and are humble and cautious when interpreting results.

Without a control or comparison group, treatment effects cannot be distinguished from other causes of clinical change (Table 7.4) (9). Some of these causes are found in Figure 7.1, which depicts change in health status after a healing encounter as a complex interaction of three primary factors:

1. *What was actually done*. Specific effect(s) of therapy, including medications, surgery, physical manipulations, and alternative or integrative approaches.
2. *What would have happened anyway*. Spontaneous resolution, including natural history, random fluctuations in disease status, and regression to a mean symptom state.
3. *What was imagined to be done*. Placebo response, defined as a change in health status resulting from the symbolic significance attributed by the patient (or proxy) to the encounter itself (10).

A placebo response is most likely to occur when the patient receives a meaningful and personalized explanation, feels care and concern expressed by the healer, and achieves control and mastery over illness (or believes that the healer can control the illness).The placebo response differs from the traditional definition of placebo as an inactive medical substance. Unlike the "placebo pills" in randomized trials, a placebo response can be elicited by touch, words, gestures, local ambiance, and social interactions. A valid and reliable 12-item survey, the PR-12, is available to measure aspects of the placebo response in office encounters (11).

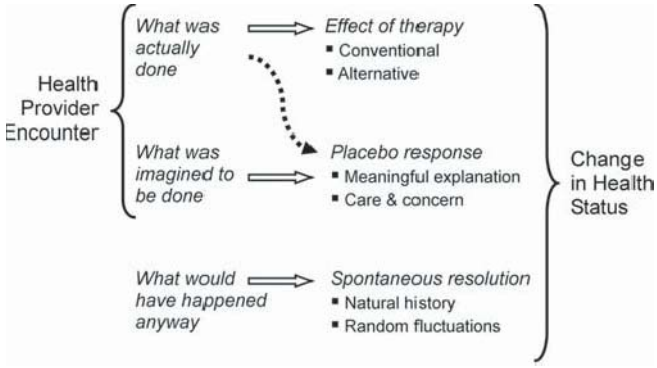

Figure 7.1 Model depicting change in health status after a healing encounter. *Dashed arrow* shows that a placebo response may occur from symbolic significance of the specific therapy given or from interpersonal aspects of the encounter.

Assessing Causality

When data from a comparison or control group are available, statistics may be used to test hypotheses and measure associations. Causality may also be assessed when the study has a time-span component, either retrospective or prospective (Table 7.3). Prospective studies measure *incidence* (new events) whereas retrospective studies measure *prevalence* (existing events). Unlike time-span studies, cross-sectional inquiries (surveys, screening programs, evaluations of diagnostic tests) measure association, not causality.

Efficacy and causality are best assessed by randomized controlled trials, because nonrandom treatment assignment is prone to innate distortions caused by individual judgments and other selective decisions (allocation bias). A dangerous habit, however, is to label all randomized trials as high quality and all observational studies (e.g., outcomes research) as substandard. Randomization cannot compensate for imprecise selection criteria, poorly defined endpoints, inadequate follow-up, or low compliance with treatment. Moreover, randomized trials with inadequate methodology tend to exaggerate treatment effects compared with trials that are properly designed and executed (12).

The best randomized trials ensure adequate randomization, conceal treatment allocation (blinding), and analyze results by intention-to-treat. The intention-to-treat analysis maintains treatment groups that are similar apart from random variation, which may not occur if only subjects who complied with treatment (on-treatment analysis) are included (13). A blinded (masked) trial is always superior to a nonblinded (open, open-label, or unmasked) trial in which everyone involved knows who received which interventions (14). In a double-blind trial the participants, investigators, and assessors all remain unaware of the intervention assignments. A triple-blind trial also maintains a blind data analysis, but some use this simply to indicate that the investigators and assessors are distinct.

Randomized controlled trials comprise only about 4% of articles in leading otolaryngology journals, with about 25% supported by industry funding (15). The presence of industry support, however, is unrelated to conclusions favoring intervention. Nearly 60% of articles use intention-to-treat analysis, but only a minority specify randomization schemes, employ a double-blind protocol, include confidence intervals (CIs), or explicitly discuss adverse events. The earlier advice of "caveat lector," therefore, also applies to randomized trials, not just observational research.

Question 2: What Are the Results?

Describing Central Tendency and Dispersion

Describing results begins by defining the *measurement scale* that best suits the observations. Categorical (qualitative) observations fall into one or more categories, and include dichotomous, nominal, and ordinal scales (Table 7.5). Numerical (quantitative) observations are measured on a continuous scale, and are further classified with a graphic display to assess distribution (histogram, stem-leaf plot, or frequency distribution curve) (16). Numerical data with a symmetric (normal or Gaussian) distribution are evenly placed around a central crest or trough (bell-shaped curve). Numerical data with an asymmetric distribution are skewed (shifted) to one side of the center or contain unusually high or low outlier values. Skewed data can sometimes be normalized with a transformation (e.g., logarithmic).

When summarizing numerical data, the descriptive method varies according to the underlying distribution. Numerical data with a symmetric distribution are best summarized with the mean (Table 7.6) and standard deviation (SD), because 68.3% of the observations fall within the mean ±1 SD, 95.4% within the mean ±2 SD, and 99.7% within the mean ±3 SD. In contrast, asymmetric numerical data are best summarized with the median, because even a single outlier can strongly influence the mean.

TABLE 7.5 MEASUREMENT SCALES FOR DESCRIBING AND ANALYZING DATA

Scale	Definition	Examples
Dichotomous	Classification into either of two mutually exclusive categories	Breast feeding (yes/no), sex (male/female)
Nominal	Classification into unordered qualitative categories	Race, religion, country of origin
Ordinal	Classification into ordered qualitative categories, but with no natural (numerical) distance between their possible values	hearing loss (none, mild, moderate), patient satisfaction (low, medium, high), age group
Numerical	Measurements with a continuous scale, or a large number of discrete ordered values	Temperature, age in years, hearing level in decibels
Numerical (censored)	Measurements on subjects lost to follow-up or in whom a specified event has not yet occurred at the end of a study	Survival rate, recurrence rate, or any time-to-event outcome in a prospective study

For example, if five patients are followed after sinus surgery for 10, 12, 15, 16, and 48 months, the mean duration of follow-up is 20 months, but the median is only 15 months. In this case a single outlier, 48 months, distorts the mean.

A special form of numerical data is called *censored* (Table 7.5). Data are censored when (a) the study direction is prospective, (b) the outcome is time related, and (c) some subjects die, are lost, or have not yet had the outcome when the study ends. Interpreting censored data is called *survival analysis*, because of its use in cancer studies where survival is the outcome of interest (17). For example, a study might report median survival time (by groups, if applicable) and the percent surviving at fixed time periods (e.g., 1, 5, 10 years). Survival analysis permits full utilization of censored observations (e.g., patients with less than 1 year of follow-up), by including them in the analysis up to the time the censoring occurred. Results of cancer studies are often reported with *Kaplan-Meier curves*, which may describe overall survival, disease-free survival, disease-specific survival, or progression-free survival (18). Survival data at the far right of the curves should be interpreted cautiously because fewer patients remain yielding less precise estimates.

Nominal and dichotomous data (Table 7.5) are best described using ratios, proportions, and rates. A ratio is the value obtained by dividing one quantity by another, both of which are separate and distinct. In a tonsillitis treatment study, for example, the ratio of children with clinical resolution after 10 days to those remaining symptomatic might be 80/20 or 4:1. In contrast, a proportion is a type of ratio in which the numerator is included in the denominator. In the previously mentioned study, the proportion with clinical resolution would be 80/100 or 0.80. Alternatively, this could be multiplied by 100 and expressed as a percentage (80%). Rates are similar to proportions except that a multiplier is used (e.g., 1,000 or 100,000) and they are computed over time. For example, a study might report a rate of 110 physician office visits per 100 children per year for upper respiratory infections.

Describing Associations

The odds ratio, relative risk, and rate difference (Table 7.6) are useful for comparing two groups of dichotomous data (19). A study of otitis media and day care might report an *odds ratio* of 1.6, indicating that a child who developed otitis media was 1.6 times more likely to have attended day care than a child with healthy ears. In contrast, a *relative risk* of 1.6 means the incidence of otitis media was 1.6 times higher in children who attended day

TABLE 7.6 DESCRIPTIVE STATISTICS

Descriptive Measure	Definition	When to Use It
Central tendency		
Mean	Arithmetic average	Numerical data that are symmetric
Median	Middle observation; half the values are smaller and half are larger	Ordinal data; numerical data with an asymmetric distribution
Mode(s)	Most frequent value(s)	Nominal data; bimodal distribution
Dispersion		
Range	Largest value minus smallest value	Numerical data without outliers
SD	Spread of data about their mean	Numerical data that are symmetric
95% reference range	Mean ± 1.96 SD	Numerical data that are symmetric
Percentile	Percentage of values that are equal to or below that number	Ordinal data; numerical data with an asymmetric distribution
Interquartile range	Difference between the 25th and 75th percentiles; contains 50% of data	Ordinal data; numerical data with an asymmetric distribution
Outcome		
Survival rate	Proportion of subjects surviving, or with some other outcome, after a time interval (1, 5 y, etc.)	Numerical (censored) data in a prospective study; can be overall, cause specific, or progression free
Odds ratio	Odds of a disease or outcome in subjects with a risk factor divided by odds in controls	Dichotomous data in a retrospective or prospective controlled study
Relative risk	Incidence of a disease or outcome in subjects with a risk factor divided by incidence in controls	Dichotomous data in a prospective controlled study
Rate difference[a]	Event rate in treatment group minus event rate in control group	Compares success or failure rates in clinical trial groups
Correlation coefficient	Degree to which two variables have a linear relationship	Numerical or ordinal data

[a]Also called the absolute risk reduction.

care versus controls who did not. Because the relative risk measures incidence, it should be used only in prospective (cohort) studies. When the frequency of events is low, however, the relative risk and odds ratio are nearly equivalent. An odds ratio or relative risk approaching unity (1.0) would suggest no association between day care and otitis media.

The *rate difference* (also called risk reduction or risk difference) may be expressed in absolute or relative terms. Suppose that initial treatment failures for acute otitis media (AOM) occur in 20% (A) of children managed expectantly but in only 10% (B) of those who receive antibiotics. The *absolute* rate difference, A – B, between groups is only 10% but the *relative* rate difference, (A – B)/B, is 100%. As a measure of clinical importance the absolute rate difference is preferred, because it is easier to interpret and takes into account the baseline risk. Relative rate differences can be deceptive, especially when event rates are low. A new antibiotic may be touted as causing 75% less gastric upset than an established standard (relative rate difference), but we are less likely to be impressed if incidence decreased from 1.00% to 0.25% (absolute rate difference of only 0.75%).

Two groups of ordinal or numerical data are compared with a *correlation coefficient* (Table 7.6). A coefficient (r) from 0 to 0.25 indicates little or no relationship, from 0.26 to 0.50 a fair relationship, from 0.51 to 0.75 a moderate to good relationship, and greater than 0.75 a good to excellent relationship. A perfect linear relationship would yield a coefficient of 1.00. When one variable varies directly with the other, the coefficient is positive; a negative coefficient implies an inverse association. Sometimes the correlation coefficient is squared (R^2) to form the *coefficient of determination*, which estimates the percentage of variability in one measure that is predicted by the other. For example, if hearing levels show an excellent correlation with duration of middle ear fluid ($r = 0.80$), then we could predict 64% (R^2) of the variability in hearing levels by knowing the fluid duration.

A final aspect of descriptive statistics concerns the reporting and interpretation of data from diagnostic tests. Important concepts in reporting test characteristics are defined in Table 7.7. Note that the sensitivity (true positive rate) and specificity (true negative rate) are fixed properties of the test. In contrast, predictive values (positive and negative) vary according to the baseline prevalence of the condition in the population where the test is applied. Last, clinicians should note that likelihood ratios are being used with increasing frequency in the medical literature. Because of space limitations, readers are referred to other sources for additional details about data from diagnostic tests (2).

Analytic Statistics

A single medical study with several groups treated differently will almost always show some difference in group outcomes. If we conclude the groups are different, we may be mistaking chance variations for treatment effects. If we conclude the groups are equivalent, we may have missed

TABLE 7.7 STATISTICAL TERMS ENCOUNTERED WITH DIAGNOSTIC TESTS

Term	Definition
Sensitivity	Ability of the test to correctly identify patients with a condition; calculated as TP/(TP + FN)
Specificity	Ability of the test to correctly identify patients without a condition; calculated as TN/(TN + FP)
Criterion (gold) standard	A method, procedure, or measurement that is widely accepted as being the best available; used as a comparison for new methods
Predictive value of a positive test	Likelihood that a patient with a positive test will actually have a condition; calculated as TP/(TP + FP)
Predictive value of a negative test	Likelihood that a patient with a negative test will actually not have a condition; calculated as TN/(TN + FN)
Likelihood ratio for a positive test	Odds of a positive test in patients with the condition vs. a positive test in patients without the condition; calculated as sensitivity/FP
Receiver operating characteristic curve	Graphic display of how well a test with a continuous outcome can discriminate among patients with and without a condition; the *y*-axis plots the TP rate and the *x*-axis plots the FP rate

FN, false negative; FP, false positive; TN, true negative; TP, true positive.

TABLE 7.8 STATISTICAL TERMS ENCOUNTERED WHEN TESTING HYPOTHESES

Term	Definition
Hypothesis	A supposition, arrived at from observation or reflection, that leads to predictions which can be tested and refuted
Null hypothesis	Results observed in a study, experiment, or test are no different from what might have occurred due to chance alone
Statistical test	Procedure used to reject or accept a null hypothesis; statistical tests may be parametric or nonparametric (distribution free)
P value	Probability of seeing the observed difference (association) or greater, just by chance, if the null hypothesis is true
Type I (alpha) error	Rejecting a true null hypothesis; declaring that a difference exists when in fact it does not; probability of a type I error is the *P* value
Type II (beta) error	Accepting a false null hypothesis; declaring that a difference does not exist when in fact it does
Power	Probability that the null hypothesis will be rejected if it is indeed false; mathematically, power is 1.00 minus type II error

a true difference. In statistical lingo (Table 7.8), we begin with some testable *hypothesis* about the groups under study, such as "Gibberish levels in Group A differ from those in Group B." Rather than keep it simple, we now invert this to form a *null hypothesis*: "Gibberish levels in Group A are equal to those in Group B." Next we fire up a computer, enter the gibberish levels for the subjects in both groups, choose an appropriate statistical test, and wait for the omnipotent *P* value to emerge.

The *P value* tells us the probability making a *type I error*: rejecting a true null hypothesis. In other words, if $P = 0.10$ we have a 10% chance of being wrong (false positive) when we declare Group A differs from Group B. Alternatively, there is a 10% probability that the difference in gibberish levels is explainable by random error—we can't be certain that uncertainty isn't the cause. Uncertainty is present in all data, because of the inherent variability in biologic systems and our ability to assess them in a reproducible fashion (20). Since we can never avoid uncertainty entirely in measurements and observations, we instead estimate the probability (*P* value) that observed results are consistent with unavoidable random variations or fluctuations.

In medicine, $P < 0.05$ is generally considered low enough to safely reject the null hypothesis. Recall, however, that when P approaches 0.05 a researcher who accepts a "significant" result as real will be wrong 5% of the time (type I error) (21). Only *P* values *much smaller than 0.05* provide strong evidence against the null hypothesis. Conversely, when $P > 0.05$ we accept the null hypothesis of equivalent gibberish levels. Nonetheless, we may be making a *type II error* (false negative) because we studied too few subjects to overcome the random fluctuations that inevitably exist. Type II error rates of up to 20% are generally acceptable, which is equal to statistical power of 80% or higher (Table 7.8).

As an example of statistical inference, consider a prospective study to see if ice cream causes sneezing. Suppose that 80% of ice cream eaters (16/20) begin sneezing but only 50% of controls (10/20). If we infer that, based on these results in 40 specific patients, ice cream causes sneezing *in general*, what is our probability of being wrong (type I error)? Because $P = 0.10$ (Fisher's exact test) there is a 10% chance of type I error, so we are reluctant to associate ice cream with sneezing based on this single study: the strength of evidence *against* the null hypothesis is simply too much to ignore.

Intuitively, however, a rate difference (absolute) of 30% seems meaningful, so what is our chance of being wrong when concluding it is not? The probability of a type II error is 48% (same as saying 52% power), which means we may indeed be wrong in accepting the null hypothesis. Now suppose we repeat this study with twice as many subjects, and 80% of ice cream eaters (32/40) start sneezing compared with 50% of controls (20/40). The rate difference is still 30%, but now $P = 0.01$. Increasing the sample size allowed us to exclude chance variations as responsible for the observed findings; the strength of evidence against the null hypothesis is now much higher.

Studies with "negative" findings should be interpreted by their statistical power, not by *P* values. There is a big difference between *observing* nothing in a study and *proving* that nothing really happened. Most often, not enough patients were studied to offer a reasonable chance of not missing differences of up to 50% between groups. Even randomized trials in otolaryngology journals, with a median samples size of only about 50 patients, suffer from low statistical power and potential "false negative" results (15). An ideal study has high power, making it likely to detect differences that exist. If no differences are detected, then the researcher can conclude with reasonable confidence that none exists in reality.

Higher power is generally achieved by increasing sample size. Calculating sample size before beginning a study ensures that the planned number of observations will offer a reasonable chance (power) of obtaining a clear answer at the end (22). The basic ingredients needed to calculate sample size include the smallest difference that must be detected between the groups (minimal clinically important difference), the variability (SD) of this difference (if the measurement scale is numerical), the limit of tolerance for a type I error (typically 5% or 1%), and the limit of tolerance for a type II error (typically 20% or 10%) (23).

Statistical Significance versus Clinical Importance

The next logical question after "Is there a difference?" (statistical significance) is "How big a difference is there?" (*clinical importance*). For example, a randomized trial of nonsevere AOM found amoxicillin superior to placebo as initial treatment ($P = 0.009$). Before we accept the authors' recommendation for routine amoxicillin therapy, let's look more closely at the magnitude of clinical effect. Initial treatment success occurred in 96% of amoxicillin-treated children versus 92% of controls, yielding a 4% rate difference (96% minus 92%) favoring drug therapy. Is this clinically important? Although statistically significant, the rate difference seems small; intuitively we suspect that many children will need treatment to benefit only a few. The next few paragraphs reveal exactly how many.

Statistically significant results must be accompanied by a measure of *effect size*, which reflects the magnitude of difference between groups (2,19). Otherwise, findings with minimal clinical importance may become statistically significant when a large number of subjects are studied. In the above example, the 4% difference in success rates was highly statistically significant because over 1,000 episodes of otitis media were analyzed. Large numbers provide high precision (repeatability), which in turn reduces the likelihood of a type I error. The final result is a hypnotically tiny *P* value, which may reflect a clinical difference of trivial importance. A *P* value of 0.000001 with a rate difference of 5% is much less clinically relevant than a *P* value of 0.01 with an absolute rate difference of 25%.

A useful measure of effect size is the *number needed to treat* (NNT), which is simply the reciprocal of the absolute rate difference (or risk reduction) (2). The NNT reflects the amount of clinical effort that must be expended to achieve one additional treatment success, and is easily calculated by dividing 100 by the absolute rate difference. For example, in the study cited above, the NNT would be 25 (100% divided by 4%). Consequently, we must treat 25 children on average with amoxicillin to increase the resolution rate of nonsevere AOM by one child above what would occur from placebo alone. What constitutes an important NNT magnitude depends on disease severity and treatment side effects. An NNT of 25 might be unimpressive for AOM, but headline news for cancer survival.

Similar to the NNT, we can also calculate the *number needed to harm* (NNH). For example, if a new antibiotic causes diarrhea in 20% of patients, the NNH is 5 (100/20). Although this drug may have other beneficial effects, they would need to be significant to justify one new case of diarrhea for every five people who use it. For example, oral antibiotics and steroids have short-term benefits for otitis media with effusion (NNTs of 4 to 7), but are not recommended in national guidelines because of adverse effects. Unfortunately, only about 40% of randomized trials adequately report clinical adverse events (12).

Relative measures of effect size (relative risk, odds ratio, relative rate difference) provide limited information in clinical trials because they do not reflect changes in baseline risk. For example, a relative risk of 50% may mean that the treatment decreases the chance of an unfavorable outcome from 4% to 2% or from 60% to 30%. Conversely, the absolute rate difference and NNT reflect both the baseline risk and degree of relative risk reduction. In the AOM trial above, the absolute decrease in treatment failures because of amoxicillin therapy was only 4% using the rate difference but an impressive 50% using the relative risk! Not surprisingly, most clinicians rate the effectiveness of an intervention lower when presented in absolute terms rather than using relative measures. Since published trials rarely provide an NNT or rate difference, readers will often have to calculate it on their own based on the absolute difference in group outcomes (24).

Question 3: Are the Results Valid within the Study?

Internal Validity

A critical aspect of understanding data is determining the validity of the research, which is a two-step process: deciding if (a) the results are and conclusions are credible for the study sample (e.g., within the study) and (b) the results and conclusions can be generalized and applied to others (e.g., outside the study sample) (3). These two questions are the topics of this and the following section, and address the issues of internal and external validity, respectively.

When a study is internally valid we conclude that the results obtained are due only (or at least, primarily) to the effect under study and are free of substantial distortions caused by improper study design, measurement errors, sloppy data collection, flawed outcome assessment, or inappropriate statistical analysis, Principles of study design, describing data, and determining significance (statistical and clinical) are covered in earlier sections and are not discussed again. Instead, we focus on bias and selecting the right statistical test for analyzing data.

Valid measurements are unbiased (free of systematic error) and reflect what they intend to measure. If a faulty audiometer consistently gives readings that are off by 15 decibels, the readings are precise (repeatable), but inaccurate (biased). Bias is not limited to faulty

instruments but may also be introduced unconsciously by study investigators (Table 7.4) through the power of suggestion (placebo effect), by using fancy equipment in impressive settings (halo effect), preferentially assigning patients with the best prognosis to the treatment group (allocation bias), or by favoring the treatment group when assessing outcomes and analyzing the data (ascertainment bias).

Questionnaires and quality of life surveys are particularly prone to bias if they have not been assessed for reliability, validity, and responsiveness (25). Unless the authors used a "validated" measure the results are suspect, but problems may also arise if a validated instrument is used in an intended way. For example, some surveys are developed specifically to compare individuals at a point in time (discriminative surveys) and may or may not be valid when used to measure change in status within individuals before and after intervention (evaluative surveys). Additional bias may arise in survey research related to sampling the population, administering the questionnaire, and managing the resultant data (26).

Bias affects not only data measurements but can creep into a study at any stage of design, conduct, analysis, or publication (7). For example, patients often have illnesses or comorbid conditions unrelated to the disease under study that can impact diagnosis, treatment, or outcomes. When these factors are significant, adjustments for comorbidity are needed to avoid confounding.

Choosing the Right Statistical Test

All statistical tests have a common purpose (to measure error), which cannot be fulfilled unless the right test is used for the data being analyzed. To determine if the right statistical test was used you must first check (a) whether the observations come from independent or related samples, (b) whether the purpose is to compare groups or to associate an outcome with one or more predictor variables, and (c) the measurement scale of the variables. Tables 7.9 and 7.10 can then be used to find the right statistical test for valid analysis.

Two events are independent if the occurrence of one is in no way predictable from the occurrence of the other. A common example of *independent samples* is two or more parallel (concurrent) groups in a clinical trial or observational study. Conversely, *related samples* include paired organ studies, subjects matched by age and sex, and repeated measures on the same subjects (e.g., before and after treatment). Sometimes, the situation is unclear, as when ears (not patients) are the unit of analysis. There are often large differences in left versus right Eustachian tube function, which is more related to a given ear than a specific child. Therefore, to analyze ears as independent samples (which often occurs to inflate sample size) may bias results.

The tests in Tables 7.9 and 7.10 labeled as "parametric" assume an underlying symmetric distribution for the data or a relatively large sample size (about 20 or more observations per group). A statistical test, the Kolmogorov-Smirnov

TABLE 7.9 STATISTICAL TESTS FOR INDEPENDENT SAMPLES

Situation	Parametric Test	Nonparametric Test
Comparing two groups of data		
Numerical scale	*t*-Test	Mann Whitney *U* test,[a] median test
Numerical (censored) scale	Mantel-Haenszel life table	Wilcoxon, Logrank, Mantel-Cox
Ordinal scale	—	Mann Whitney *U* test,[a] median test, chi-squared test for trend
Nominal scale	—	Chi-squared, log-likelihood ratio
Dichotomous scale	—	Chi-squared, Fisher's exact test, odds ratio, relative risk
Comparing three or more groups of data		
Numerical scale	One-way ANOVA	Kruskal-Wallis ANOVA
Ordinal scale	—	Kruskal-Wallis ANOVA, chi-squared test for trend
Dichotomous or nominal scale	—	Chi-squared, log-likelihood ratio
Associating an outcome with predictor variables		
Numerical outcome, one predictor	Pearson correlation	Spearman rank correlation
Numerical outcome, two or more predictor variables	Multiple linear regression, two-way ANOVA	—
Numerical (censored) outcome	Proportional hazards (Cox) regression	—
Dichotomous outcome	Discriminant analysis	Multiple logistic regression
Nominal or ordinal outcome	Discriminant analysis	Log-linear model

ANOVA, analysis of variance.
[a]The Mann Whitney *U* test is equivalent to the Wilcoxon rank-sum test.

TABLE 7.10 STATISTICAL TESTS FOR RELATED (MATCHED, PAIRED, OR REPEATED) SAMPLES

Situation	Parametric Test	Nonparametric Test
Comparing two groups of data		
Dichotomous scale	—	McNemar's test
Ordinal scale	—	Sign test, Wilcoxon signed rank test
Numerical scale	Paired *t*-test	Sign test, Wilcoxon signed rank test
Comparing three or more groups of data		
Dichotomous scale	—	Cochran *Q* test, Mantel-Haenszel chi-squared
Ordinal scale	—	Friedman ANOVA
Numerical scale	Repeated measures ANOVA	Friedman ANOVA

ANOVA, analysis of variance.

test, can be used to measure the "normalcy" of numerical data ($P > 0.05$ indicates that parametric methods are appropriate) (16). If the data are sparse, asymmetric, or ordinal, then a *nonparametric test* must be used. Nonparametric tests rank the observations in order of magnitude, and then compare the ranks not the measurements themselves. Compared with traditional tests, however, nonparametric tests lack power and offer less meaningful estimates of effect size (27).

Another feature of Tables 7.9 and 7.10 is that special tests are required to compare three or more groups of data. Recall that every "significant" statistical test has some possibility of type I error (false positive) defined by the *P* value. If we study three groups and analyze the data with three pairwise comparisons (A vs. B, B vs. C, A vs. C) the combined type I error rate is 14% assuming a 5% rate for each individual comparison. Studying four groups yields six possible pairwise comparisons with a combined error rate of 27%. Analysis of variance avoids this problem by providing a single overall test of differences between groups or treatments (28). Special techniques allow multiple comparisons between groups.

Here are some brief examples to illustrate statistical test selection. Assume we are comparing patient satisfaction for two different treatments using a 5-point outcome scale (poor, fair, good, very good, excellent). According to Table 7.9, the correct test for two groups of independent ordinal data is the Mann Whitney *U* test (Wilcoxon rank-sum is equivalent). If the investigators instead used a *t*-test, results might be invalid. Now suppose we wish to compare hearing levels (numerical scale) before and after stapedectomy for 50 patients. Using Table 7.10 (we are dealing with a matched sample) we note a paired *t*-test or Wilcoxon signed-rank test could be used. Finally, if we wanted to associate survival after tumor resection (a censored outcome) with several predictor variables (e.g., age, type of surgery, comorbidity, TMN stage) we would use proportional hazards (Cox) regression (Table 7.9).

Proper selection of statistical tests can never compensate for flaws in study design. Suppose we measure intelligence quotient (IQ) in 200 children before and after tympanostomy tubes, and find a mean IQ increase of 10 points per child. We *can* conclude that the improvement is unlikely to be fortuitous ($P = 0.01$, matched *t*-test), but we *cannot* be certain what caused it. Stated differently, improvement *after* surgery (or any intervention) does not necessarily imply improvement *because* of surgery. More likely the change in IQ was not a real increase, but bias caused by learning from the first test. Without a control group, we cannot determine what part of the change (if any) was caused by tubes.

A fundamental assumption underlying all statistical tests is that the hypothesis under study was fully developed before the data were examined in any way. Consider the Texas sharpshooter who shoots an arrow at a barn wall, then meticulously draws a bulls eye around it. When hypotheses (or bulls eyes) are formulated *post hoc*—after even the briefest glance at the data—the basis for probability statements (or shooting accuracy) is invalidated. All statistical tests are based on assumptions about the distribution, variability, and relationships of the underlying data that invalidate results if violated. Specific assumptions apply to comparing means, correlation, and regression.

Last, an internally valid study not only uses the right statistical test for the data but also reports the results in a clear, coherent, and complete manner. Since proper reporting varies according to the data format (Table 7.5) and specific test used (Tables 7.9 and 7.10) the reader is referred elsewhere for details (29), which should generally appear in one or more well-constructed tables in the research manuscript.

Question 4: Are the Results Valid Outside the Study?

Having first determined that the investigator's conclusions correctly describe what happened *inside* the study (Question 3), the next task is to determine if they can

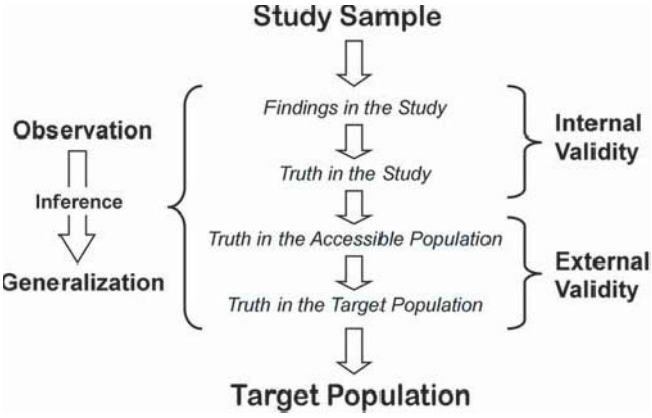

Figure 7.2 Flow chart showing the relationships of validity, sampling, and inference. Not all internally valid studies are externally valid and vice versa. See Table 7.11 for definitions of individual terms.

be applied (generalized) to the universe *outside* the study (Fig. 7.2). Unfortunately, not all well-conducted, internally valid studies have *external validity* (generalizability or applicability). This distinction is nontrivial, because the key question from the clinician's viewpoint is "Can I apply the results of this study to the patients I see in my practice?" For the answer to be "yes," the sampling method must be sound, the subjects studied must be representative of the target population, and the sample size must be large enough to instill confidence in the results.

Sampling a Population

When we interpret medical data, we ultimately seek to make *inferences* about some target population based on results in a smaller study sample (Table 7.11). Rarely is it possible to study every subject with the condition of interest. Nor is it necessary—statistics allow us to generalize from the few to the many, provided that the few are *representative* of the many. However, representative samples rarely arise from divine providence. Review carefully the inclusion and exclusion criteria (check the article's methods section) to be sure that the subjects studied are representative of those in whom you wish to apply the results. A study with vague subject selection criteria may yield fascinating results, but we have no way of knowing to whom they apply.

Consider, for example, a randomized trial of early versus delayed tympanostomy tubes for persistent otitis media that concluded early tube insertion did not improve developmental outcomes at 3 years of age. To whom do these results apply? The 429 randomized children with persistent effusion were culled from a birth cohort of 6,350 healthy infants examined at least monthly for 3 years; if not in the study many of these children would never have received tubes because their middle-ear effusion was transient, asymptomatic, or unilateral. In contrast, study participants received tubes based solely on cumulative effusion prevalence (identified with regular, intensive screening), not based on hearing levels or other otitis media signs and symptoms. Therefore, the ability to generalize these results beyond asymptomatic, otherwise healthy infants identified with aggressive screening is unknown.

Having determined that the target population and subject selection criteria are meaningful, the next step in judging external validity is to assess how the study sample was selected. Investigators typically have access to only a small subset of the target population because of geographic, temporal, or demographic constraints. When they choose an even smaller subset of this *accessible population* to study (Table 7.11; Fig. 7.2), the method of choosing (sampling method) affects their ability to make inferences about the

TABLE 7.11 STATISTICAL TERMS RELATED TO SAMPLING AND VALIDITY

Term	Definition
Target population	Entire collection of items, subjects, patients, observations, etc., about which we want to make inferences; defined by the selection criteria (inclusion and exclusion criteria) for the study
Accessible population	Subset of the target population that is accessible for study, generally because of geographic or temporal considerations
Study sample	Subset of the accessible population that is chosen for study
Sampling method	Process of choosing the study sample from the larger accessible population
Selection bias	Error caused by systematic differences between a study sample and target population; examples include studies on volunteers and those conducted in clinics or tertiary care settings
Inference	Developing a generalization based on data from a study sample, usually with calculated degrees of uncertainty
Internal study validity	Degree to which conclusions drawn from a study are valid for the study sample; results from proper study design, unbiased measurements, and sound statistical analysis
External study validity (generalizability)	Degree to which conclusions drawn from a study are valid for a target population (beyond the subjects in the study); results from representative sampling and appropriate selection criteria

original target population. Unless an appropriate sampling method is used, the study sample may differ systematically from the intended target population (selection bias).

The best sampling method is to randomly select members of the accessible population. Bias is minimized because all subjects have a known (and equal) probability of selection, but random sampling is rarely feasible in most clinical research studies. Fortunately, a consecutive or systematic sample offers a relatively good approximation. Consecutive samples are common, and include all subjects over a specified time interval or until a specified sample size is reached. Systematic samples are obtained using some simple, systematic rule, such as day of week, date of birth, or first letter of last name. The worst sampling method occurs when subjects are chosen based on convenience or subjective judgments about eligibility by the investigators. Convenience (grab) sampling should be assumed when no other method is specified.

Random allocation of patients to treatment groups differs from random sampling of a population. Randomization improves internal validity by reducing allocation bias (Table 7.4), but has no impact on external validity. Most randomized trials, however, have rigid and restrictive subject selection criteria that tend to limit generalizability compared to less restrictive outcomes-type studies.

Precision and Confidence Intervals

Another component of external validity is *precision*, which reflects the degree of variability in the observations. Variability (precision) must be dealt with when interpreting data, unless the results are meant to apply only to the particular group of patients, animals, cell cultures, DNA strands, etc., in which the observations were initially made. Recognizing this limitation, we call each of the descriptive measures in Table 7.6 a *point estimate*, specific to the data that generated it. In medicine, however, we seek to pass from observations to generalizations, from point estimates to estimates about other populations. When this process occurs with calculated degrees of uncertainty, we call it *inference*.

Here's a brief example of clinical inference. After administering Echinacea to five patients with Ménière disease you remark to a colleague that four had excellent relief. She asks, "How confident are you of your results?" "Quite confident," you reply, "there were 5 patients, 4 got better, and that's 80%." "Maybe I wasn't clear," she interjects, "how confident are you that 80% of patients with Ménière disease you see in the next few months will respond favorably, or that 80% of similar patients in my practice will do well with Echinacea?" "In other words," she continues, "what can you *infer* about the *real* effect of Echinacea from experience with only 5 patients?" Hesitatingly you retort "I'm pretty confident about that number 80%, but maybe I'll have to see a few more patients to be sure."

The real issue, of course, is that a sample of only five patients offers low *precision* (repeatability). How likely is it that the same results would be found if five new patients were studied? Actually, we can state with 95% confidence that four successes out of five in a *single* sample is consistent with a success rate of 28% to 99% in *other* samples of five patients from the accessible Ménière population. This *95% confidence interval* (CI) may be calculated manually, with a statistical program or with numerous applications and calculators accessible on the internet (23).

What is the best way to conceptualize and understand confidence intervals? Simply stated, a CI offers a *zone of compatibility* with the data (30). In the Ménière example above, a 95% CI of 28% to 99% tells us that we do not know much about the real outcome of therapy, because a single study with four patients is compatible with a very broad range of results. Stated differently, the results lack precision; the range of values that are considered plausible for the population is too large to really know what to expect in the future (31). In statistical terms, a CI tells us the range of *sample means* consistent with the observed data, but this type of explanation rarely helps clinicians in understanding, or communicating, the concept (32).

Precision may be increased (uncertainty may be decreased) by using a more reproducible measure, by increasing the number of observations (sample size), or by decreasing the variability among the observations. The most common method is to increase the sample size, because we can rarely reduce the variability inherent in the subjects we study. If 50 patients (instead of 5) received Echinacea and 40 had symptomatic relief, the 95% CI for success narrows to between 66% and 90%. The point estimate, however, remains 80% (40/50). Although we are more confident in our results following this larger trial (e.g., the zone of compatibility is tighter), we cannot say anything about the *efficacy* of Echinacea without an untreated control group for comparison.

Realizing that uncertainty can never completely be avoided, we use statistics to estimate precision. Thus, when data are described using the summary measures listed in Table 7.6, a corresponding 95% CI should accompany each point estimate. When the study reports "positive" findings ($P < 0.05$), the *lower* limit of the interval should be scrutinized; if it is less than what you consider to be a clinically important effect size then precision is inadequate. When the study reports "negative" findings ($P > 0.05$), the *upper* limit of the interval should be checked; if it is consistent with a clinically important effect size then statistical power is inadequate.

As an example of CI interpretation, consider an evidence report on AOM that found an absolute rate difference of 12.3% (95% CI: 2.8% to 21.8%) favoring amoxicillin over placebo. Since the lower limit of the CI is 2.8%, which may not be clinically important, the precision is less than optimal. The 95% CI for the NNT is easily calculated (see above) as 4.6 to 35.7, which again shows the results are consistent with a need to treat up to 36 children to benefit one. The findings suggest a significant benefit of antibiotics

for some children with AOM (95% CI does not contain zero), but the imprecision and modest NNT argue for selective and judicious therapy.

When a study reports "no significant difference" the CI can help determine if something might have been missed (low power). For example, a meta-analysis of streptococcal pharyngitis concludes that short-course antibiotic (5 to 7 days) is equivalent to full-course (10 days) because the odds ratio for treatment failure is 1.00 (95% CI: 0.50 to 1.50). Whereas the point estimate of 1.0 suggests equivalency, the 95% CI is consistent with sample means from 0.50 (half as many failures with short-course therapy) up to 1.50 (twice as many failures with short-course therapy). Thus, we have insufficient data to conclude with reasonable certainty that short-course therapy is comparable to full course.

The examples above clarify why describing study results as simply statistically "significant" or "nonsignificant" is unacceptable (33). A *P* value measures strength of evidence against the null hypothesis, but offers no information on effect size. A *P* value approaching 0.05 often has precision that is too low to exclude a trivial effect and a "nonsignificant" *P* value often has an associated 95% CI that contains clinically important sample means. Studies with narrow CIs have high precision, and are most meaningful regardless of the *P* values. Conversely, studies with broad CIs require careful scrutiny.

Question 5: Are the Results Strong and Consistent?

The first step in assessing strength and consistency is asking "Do the results make sense?" Significant findings that are biologically implausible, or that are inconsistent with other known studies, can often be explained by hidden biases or design flaws, which were initially unsuspected. Improbable results can become statistically significant through biased data collection, natural history, placebo effects, unidentified confounding variables, or improper statistical analysis. A study with design flaws or improper statistical analysis has low internal validity and should be reanalyzed or discarded.

At the next level of integration, we compare the study design that produced the current data with the design of other published studies. The *level of evidence* generally increases as we progress from observational studies to controlled experiments (randomized trials) (2). For example, if several randomized efficacy trials have already been published about the topic of interest, an uncontrolled study is unlikely to provide any new insights. Conversely, for populations in which randomization is unethical, a well-designed cohort study may be the best attainable evidence. When a certain level of evidence has been accumulated, causation may be inferred. *Causation* is an epidemiologic concept based on the consistency, strength, specificity, and temporal relationship of the association between a factor and a particular disease or outcome (34).

When assessing the level of evidence, readers must realize that certain study designs are more suited than others to answer specific clinical questions (Table 7.12) (35). *Therapy* questions, which seek to determine the effect of different treatments on outcomes, are best answered with randomized controlled trials, which ideally have been synthesized using systematic review. Questions about *diagnostic tests* are best answered using cross-sectional designs in which patients with and without the condition of interest undergo both the new diagnostic test and an established, consistently applied, gold (criterion) standard. *Prognosis* questions are addressed by observing groups of patients with and without baseline risk factors over time in a prospective cohort design. Last, if the study focus is about *prevalence* or *incidence*, a local or current random sample survey (or census) is best.

A single study—no matter how elegant or seductive—is rarely definitive. Science is a cumulative process that requires a large body of consistent and reproducible evidence before conclusions can be formed. For this reason, achieving the highest level of evidence (Table 7.12) often requires a *systematic* review of available evidence, using explicit and reproducible criteria to assemble, appraise, and combine articles with a minimum of bias (36). Meta-analysis is a form of systematic review that uses statistical techniques to derive quantitative estimates of the magnitude of treatment effects and their associate precision (37). Valid systematic reviews (and meta-analyses) address focused questions, assess the quality and combinability of articles, provide graphic and numeric summaries, and can be generalized to a meaningful target population. They also contain a flow diagram showing the fate of articles as they pass through different phases of the review process, including identification, screening, eligibility, and inclusion (38).

Clinical practice guidelines are encountered with increasing frequency in the otolaryngology literature and may be defined as "statements that include recommendations intended to optimize patient care that are informed by a systematic review of evidence and an assessment of the benefits and harms of alternative care options" (39). Guidelines, therefore, build upon systematic reviews by incorporating values, preferences, and recommendation strengths, ideally based upon explicit and transparent processes that represent all stakeholders, including consumers (40). The best guidelines contain a limited number of actionable recommendations supported by distinct evidence profiles, such as the tonsillectomy guideline released by the American Academy of Otolaryngology—Head and Neck Surgery in 2011 (41).

In summary, all scientific data are plagued by errors, biases, and uncertainties. Statistical analysis minimizes sampling error and appropriate study design minimizes bias. Uncertainty is a more difficult problem, but can be partially reduced with humility and 95% CIs. Glimpses of association and causation emerge as the level of evidence increases and a critical mass of high-quality, combinable studies is achieved. A sufficient evidence base facilitates clinical practice guidelines that enable optimal patient care

TABLE 7.12 LEVELS OF EVIDENCE[a]

Level[b]	Treatment Benefits	Prevalence or Incidence	Prognosis	Diagnostic Test Assessment
1	Systematic review of randomized trials or *n*-of-1 trials	Local and current random sample surveys (or censuses)	Systematic review of inception cohort studies[c]	Systematic review of cross-sectional studies with consistently applied reference standard and blinding
2	Randomized trial or observational study with dramatic effect	Systematic review of surveys that allow matching to local circumstances	Inception cohort studies[c]	Individual cross-sectional studies with consistently applied reference standard and blinding
3	Nonrandomized controlled cohort or follow-up study	Local nonrandom sample	Cohort study or control arm of randomized trial	Nonconsecutive studies, or studies without consistently applied reference standards
4	Case-series, case–control studies, or historically controlled studies	Case-series	Case-series or case–control studies, or poor quality prognostic study	Case–control studies, or studies with a poor or nonindependent reference standard
5	Mechanism-based reasoning from physiology, bench research, first principles, or expert opinion

[b]Level may be graded down based on study quality, imprecision, indirectness, inconsistency between studies, or because the absolute effect size is very small; level may be graded up if there is a large or very large effect size.
[c]Inception cohort: group of individuals identified for subsequent study at an early, uniform point in the course of the specified health condition, or before the condition develops.

by making recommendations based on levels of evidence and harm–benefit ratios. Clinicians can best understand and benefit from this dynamic flow of ideas through an enlightened approach to understanding data and interpreting the medical literature.

HIGHLIGHTS

- The peer-reviewed medical literature generally serves science, not medical practice; critical appraisal is needed to locate clinically relevant and valid evidence
- Critical appraisal begins with the principles outlined in Tables 7.1 and 7.2, with emphasis on the magnitude, clinical relevance, and generalizability of the main results
- Study design has a profound impact on validity; answer the questions in Table 7.3 before attempting to interpret or apply results
- Improvement after therapy does not always equate with improvement because of therapy; unless the study is controlled and randomized, bias, chance, or natural history (Table 7.4) may account for apparent "efficacy" of the intervention
- Statistical analysis involves describing results, selecting the right test based on the nature of the variables and questions being asked, and addressing clinical importance (Tables 7.5 to 7.10)
- A properly performed and analyzed study has internal validity, but the ability to generalize results beyond the study (external validity) depends on sampling and subject selection criteria
- No amount of statistical wizardry can compensate for flawed study design, poorly collected data, and biased outcome assessment; *P* values and CIs deal with sampling error, not bias

8 Outcomes Research and Evidence-Based Medicine

Michael G. Stewart

INTRODUCTION AND HISTORY

Outcomes research can be defined as the scientific study of the outcomes of disease therapies used for a particular disease, condition, or illness (1). While all clinical research measures some type of outcome, such as mortality, morbidity, or some other objective measure, in "outcomes research," the patient's perception of their outcome is assessed.

Historically, the movement toward outcomes-based research was started by Dr. Paul Ellwood, who in the 1980s suggested that in the future physicians would assess outcomes by measuring what the patient experienced (2). Subsequently, tools to assess these outcomes were developed and applied across many diseases. However, outcomes research also includes other types of studies in addition to patient-based outcomes studies. Today, outcomes researchers study all aspects of the health care system—from the status of the patient or population at entry, to the organization, delivery, regulation and financing of the health care system, to the status of the patient or population after treatment.

To be inclusive of other aspects of health services research, some have divided outcomes research into *record-based* outcomes research and *patient-based* outcomes research. Examples of these different types of studies are shown in Table 8.1.

DEFINITION OF OUTCOME

Traditional clinical outcomes, such as survival and complication rate, are still assessed in outcomes research. However, emphasis is placed on *expanded* measures of outcome, which primarily are assessed from the patient's perspective. These expanded outcomes include quality of life, global health status, and disease-specific health status. In addition, assessment of other factors that might impact outcome, such as comorbid disease, should also be assessed. Outcomes assessment is discussed in more detail later in the chapter.

Another significant difference between traditional clinical research and outcomes research is that outcomes studies are often performed in "real-world" settings using larger groups of patients versus traditional clinical research where typically smaller groups of patients are studied under very controlled environments.

TYPES OF STUDIES

Prospective, retrospective, or cross-sectional study designs can be used in outcomes research. However, many outcomes studies use an *observational* prospective design, where outcomes are assessed after diverse treatments—rather than an *experimental* prospective design, where treatments are carefully controlled or randomized. The differences between these study designs are an important point for discussion.

In experimental or controlled trials, particularly randomized trials, the ideal design uses two groups of patients that are nearly identical in every aspect—except the treatment received. So therefore, any difference in outcome between groups must be due only to the different treatments, since otherwise the groups were the same. Of course, acquiring patient groups that are actually identical is rarely achieved, but nevertheless, that is the basis behind the rigorous design and methodology of controlled trials. In addition, to account for the inherent differences between treatment groups, the randomization process should theoretically distribute those differences (say, in demographics or disease severity) equally between the two groups. Carefully controlled experimental studies can be said to measure the *efficacy* of treatment, under ideal circumstances. These studies usually yield very reliable results concerning the effects of treatment—in the group that was studied.

TABLE 8.1 TYPES OF OUTCOMES RESEARCH

Record-based outcomes research

- Meta-analysis
- Appropriateness research
- Reviews of administrative databases
- Population-based studies

Patient-based outcomes research

- Development of quality of life and health status instruments
- Development of disease severity stratification systems
- Longitudinal outcomes studies
  - Prospective
  - Retrospective
  - Observational

Modified from Rosenfeld RM, Bluestone C, eds. *Evidence-based otitis media*. Hamilton, ON: BC Decker, Inc., 1999:51–60, with permission.

However, there are questions about the generalizability of results from rigorously controlled trials to larger populations of patients with a disease because the larger group of patients will not be so carefully controlled and homogeneous. In addition, patient compliance and other factors may lead to different results than in tightly controlled trials. Furthermore, clinical trials are very expensive to perform, especially when considered from the standpoint of cost per patient studied.

Observational study designs are commonly used in outcomes research. All patients with a disease are included, and they are studied in the actual setting in which they receive their health care. This naturally introduces many other factors, which may impact outcome after treatment, including potential selection bias for different treatments. However, many would argue that results from large-scale outcome studies are more applicable to the general population because of their setting and scope. Studies that assess the actual ("real world") results of treatment are said to measure the *effectiveness* of treatment versus *efficacy* measured from controlled trials (3). Furthermore, in addition to their "real-world" setting, the expanded outcome measured (quality of life, etc.) might be more relevant and important to patients than other clinical or biologic outcomes.

STEPS IN PERFORMING OUTCOMES RESEARCH

There are several basic steps involved in performing patient-based outcomes research (3–5). The fundamental steps are as follows: (a) identify and define the disease of interest, (b) create a staging system (clinical-severity index) for disease severity, (c) identify comorbid conditions, and (d) establish the outcomes to be measured (4). Studies can perform only one of those steps or some or all. Therefore, development and validation of an outcomes instrument is one type of outcomes research, and identification of comorbid conditions is another type. Each step is discussed in more detail below.

Define the Disease of Interest

This may be a straightforward step if the disease has clear and widely agreed upon diagnostic criteria. However, many diseases are difficult to rigorously define, such as gastroesophageal reflux or chronic rhinosinusitis, and research may be needed to develop clear reproducible diagnostic criteria.

Create a Staging System or Clinical-Severity Index

Grouping or stratification by disease severity is important in all types of clinical research. However, it is particularly important in outcomes research. This is because large numbers of patients may be studied without strict entry or exclusion criteria. Patients with more severe disease may receive more (or less) aggressive treatment, so it is therefore important to statistically adjust for disease severity when evaluating outcomes.

Staging systems already exist for many diseases, for example, the TNM staging system for cancer. It is important to distinguish between staging systems that are descriptive and systems that are prognostic. Descriptive staging systems simply group together patients who have similar characteristics. Prognostic systems are designed to predict an outcome; for example, the TNM staging system is designed to predict 5-year survival. In general, staging systems used for outcomes research should be prognostic (3). However, even if a prognostic staging system already exists, it may not contain all the important variables that predict outcome (5).

To develop a prognostic staging system, the researcher should first define the outcome of interest to be predicted by the staging system, which is defined as the dependent variable. Next, identify a group of variables that might predict outcome—those are the independent variables. Potential independent variables can be identified from prior literature, a prospective study, or expert opinion. Then next, perform a prospective study, identifying a heterogeneous group of subjects that is likely to contain patients with mild, moderate, and severe disease. In that group, measure the presence of all potential predictor variables and the outcomes after treatment.

Then, using data on both the outcome of interest and the presence of predictor variables, perform a multivariate analysis to identify which predictor variables actually impact outcome. Multivariate analysis is important in clinical studies because several different variables usually exert effects on each other, so it is preferable to study the effects of a large group of variables at the same time while controlling for the effects of the other potentially important variables.

Multivariate regression (linear or logistic) is one option for analysis; however, there are other options such as conjunctive consolidation (3,6,7). If regression is used, predictive factors are identified, and each can create a category with different outcomes. However, if multiple predictor variables are identified, the process of developing a single staging system can be difficult and at best requires multiple iterations of trial and analysis. The technique of conjunctive consolidation allows new clinical factors to be added to a staging system without necessarily increasing the number of groups or categories. Also, for development of a staging system, the data collection can be performed retrospectively, particularly if the outcome requires a significant time interval.

There are several potential "models" of staging systems from which to choose. Under any circumstances, developing a staging system is an iterative process in which patients are grouped by predictor variables, and the outcomes, by group, are assessed. If the groups are not sufficiently distinct, then another arrangement of predictor variables is used and outcomes by group are again compared. Ideally, the staging system should be organized so that patients are easily grouped into distinct strata, with clearly different outcomes, and such that all patients should be classifiable.

Identify Comorbid Conditions

The concept of a "comorbid" condition that seriously affected treatment outcome was first described by Dr. Alvan Feinstein. A comorbid condition is defined as a condition—distinct from the condition of interest—that affects the outcome being measured. For example, when measuring mortality from laryngeal cancer, if the patient has another serious condition causing potential mortality (i.e., unstable angina), then that condition is defined as a comorbid condition. Since the initial description, researchers in multiple specialties have identified the impact of comorbid disease on several different outcomes (6,7). Therefore, in any outcomes study, it is important to identify all potentially important comorbid conditions and to measure their presence and severity as part of the data collection process. Of course, that only applies if the comorbid condition actually affects the condition under study. Using the same example of unstable angina, if one were performing an outcomes study of hearing satisfaction 1 month after receiving different types of hearing aids, the presence of unstable angina would not necessarily be an important comorbid condition to consider.

Define the Outcomes to be Measured

The expanded, patient-based outcomes usually measured in outcomes research are quality of life, health status, and functional status. There are multiple potential definitions for each of those terms; however, "quality of life" has three key aspects: (a) it is more than the absence of disease, (b) it is subjective (assessed from the patient's perspective), and (c) it is multidimensional. In addition, the overall quality of life depends on multiple aspects of life not directly related to disease, so most researchers studying treatment outcomes are actually assessing the "health-related quality of life." Most outcomes instruments designed for use in patient care are designed to assess health-related quality of life. The term "health status" is self-explanatory, but again, it must be measured from the patient's perspective. Functional status refers to the patient's ability to perform daily activities. In most circumstances, researchers are only interested in the effect of a particular disease, so disease-specific functional status is typically assessed.

To measure functional status or quality of life, the patient must answer several questions that have been validated for the purpose of measurement. Although these data can be gathered using interviews or other interactive techniques, under most circumstances patients complete a written questionnaire. In outcomes research, the questions are called "items" and the questionnaires are called "instruments." Instruments must be validated, and the validation process uses the scientific principles of psychometrics. A full discussion of the process of instrument validation would require more than one chapter, although the basic concepts are reviewed.

A health status or quality of life instrument should be reliable, valid, and sensitive (8). Two types of reliability are usually assessed—test–retest reliability and internal consistency reliability. Test–retest reliability means that the results will be similar if the status of the patient has not changed, and internal consistency reliability means that responses on similar items will be correlated.

Validity means that the instrument is measuring what it is supposed to measure. Validity is confirmed by a combination of evidence: content validity, criterion validity (if scores on the instrument correlate with objective measurable external criteria), and construct validity (if scores on the instrument correlate with scores on other instruments measuring similar concepts).

Sensitivity (or responsiveness) means that the instrument is responsive to change in status. In other words, if the patient's clinical status changes, then their score should also change. Sensitivity is assessed using statistical techniques measuring the degree of change against known standards, such as the standardized response mean and the effect size.

Another aspect of assessing sensitivity or change in status using an instrument has been called the "minimal significant difference" in score (3). For example, average scores on a health status instrument may change from 40 to 50 (on a scale of 0 to 100), and the difference might have a p-value less than 0.05. The question arises—is that 10-point difference a *clinically* significant change? If studies have indicated that the minimal clinically significant difference for the instrument is 15 points (out of 100), then the score change does not reach a level of minimal

significant difference. Therefore, although *p*-value indicates that the 10-point difference is likely not due to chance, it is probably too small a change to be noticed clinically by a patient.

Fortunately, it is seldom necessary to develop your own instrument. There are already hundreds of quality of life and health status instruments available in the literature. Some examples of validated quality of life instruments to assess global quality of life include the Medical Outcomes Study SF-36 and SF-12, the Quality of Well-Being Scale, the London Handicap Scale, the Sickness Impact Profile, and the Child Health Questionnaire. Some disease-specific quality of life instruments for Otolaryngology include the Chronic Sinusitis Survey, the Sinonasal Outcome Test-20 items, the University of Washington Quality of Life Index, and the Voice Handicap Index.

Assuming that a validated instrument exists, the main question for a researcher becomes: which instrument to choose? This choice is usually based on the content of the instrument, and the potential respondent burden. To discuss the assessment of content, a good example is hearing loss where several validated instruments are available. Review of the design and content of those instruments indicates that some are intended to assess satisfaction with a hearing aid, one is for elderly patients only, one is designed for conductive hearing loss in the otherwise healthy patient, etc. Therefore, content can guide instrument selection.

Respondent burden deals with the length of time and effort required to complete an instrument. Particularly when multiple questionnaires are used, selecting instruments with lower respondent burden should improve patient compliance and follow-up. In addition, researchers have found that shorter instruments are usually very sensitive to change, so little is lost from the standpoint of responsiveness by using a briefer instrument.

Another important issue is whether to choose a general ("global" or "generic") quality of life/health status instrument or a disease-specific instrument. Both have advantages and disadvantages (3). Global instruments have the advantage of being comparable across disease states, and their use allows comparisons between the relative impacts of certain diseases. However, many global health status instruments are relatively insensitive to the impact of more limited disease states, which nevertheless may cause significant worsening of patients' quality of life. This might not be true for all global instruments, but this finding has been replicated in several diseases. Therefore, if a global quality of life instrument is not sensitive enough, then use of a disease-specific instrument is appropriate.

Disease-specific instruments are much more sensitive to the impact of a particular disease, and they allow meaningful comparisons between treatments or groups of patients. However, disease-specific instruments do not allow comparisons across disease states, which can be a disadvantage if the goal is to demonstrate the overall impact of a given disease. Therefore, in many circumstances, it is wise to use both a global and a disease-specific instrument (3).

Finally, as discussed previously, traditional clinical outcomes such as disease-free survival remain important outcomes for assessment. In some cases in which the traditional outcomes are well-known and only the expanded, patient-based outcomes are of interest, then perhaps only quality of life/health status might be assessed. However, if there is a minimal added burden to the patient and researcher to assess "traditional" clinical outcomes (such as disease-free survival), under most circumstances, those outcomes should also be assessed.

RESULTS FROM OUTCOMES RESEARCH IN OTOLARYNGOLOGY

Outcomes studies in Otolaryngology have yielded many important results, and some brief examples are listed here. There are now validated outcomes instruments for use in chronic sinusitis, nasal obstruction, hearing loss, chronic ear disease, tinnitus, dizziness, head and neck cancer, voice, gastroesophageal reflux, tonsil and adenoid disease, pediatric otitis media, and pediatric sleep apnea, among other diseases. In addition, there is a comprehensive prognostic staging system for obstructive sleep apnea in adults. Studies have shown that global quality of life is significantly worsened in adults with chronic rhinosinusitis and improves to near normal after endoscopic sinus surgery. Similarly, global quality of life is significantly worsened in children with tonsil and adenoid disease. We have learned that comorbid conditions have significant impact on survival and outcome in patients with laryngeal cancer and other head and neck cancers. Disease-specific quality of life has been shown to improve significantly after surgical treatment for the following conditions: chronic rhinosinusitis, pediatric otitis media, vocal cord paralysis, conductive hearing loss, nasal septal deformity, and pediatric sleep apnea, among others. In addition, cochlear implantation has been demonstrated to be very cost-effective relative to other health care interventions.

OTHER TYPES OF OUTCOMES RESEARCH

In addition to patient-based studies, other types of outcomes research have made important contributions, for example, appropriateness studies. In an appropriateness study, records from a large population are reviewed to test the hypothesis that treatment (medical or surgical) was based on appropriate indications. These studies often yield controversial results for two primary reasons. One reason is that it is difficult to achieve consensus on what is an appropriate versus equivocal versus inappropriate indication. An appropriateness study might find that a large percentage of procedures were performed for "equivocal" indications, when there is legitimate contradicting evidence

showing that those indications could have been classified as "appropriate." The second reason is that those studies rely heavily on medical record documentation, which is often insufficient. So although the patient's chart might indicate that appropriate indications were not met, in fact that particular patient might have actually met all the criteria. Despite the controversy, these studies are important because they generate discussion and can act as an impetus for further research, collaborative guideline development, etc.

Another type of outcomes research is population studies. Many important findings have been identified from studies of rates of medical care received by different populations. Of particular interest are studies that compare the rates of procedures with controversial indications. Some early examples were studies of population rates of tonsillectomy, hysterectomy, lumbar disk surgery, and carotid endarterectomy: researchers found that populations that seemed remarkably similar in demographics, economics, and health status had markedly different rates of elective procedures performed. The only apparent differences seemed to be where they lived, and the number of specialty physicians per capita in their region. Other studies have shown remarkable differences in rates of hospital admission for the same admitting diagnoses in different cities, even after controlling for many health status and demographic factors that might influence admission rate. While these studies sometimes generate more questions than answers, they give important insight into the delivery of health care.

One important example of a database/population-based study was one that compared overall survival between patients with obstructive sleep apnea who were treated with continuous positive airway pressure (CPAP) versus patients who underwent uvulopalatopharyngoplasty (9). This study was performed in the Veterans Affairs (VA) system, which has had a national computerized medical record for many years and has a consistent population of patients who receive all their care at the VA. The authors reviewed the database and identified more than 15,000 patients eligible for study. They found that—controlling for a variety of variables including severity and comorbidity—survival was better in the surgery group than the CPAP group. This seemed surprising since in head-to-head comparisons CPAP is more effective than uvulopalatopharyngoplasty. The reason for the population finding seemed to be that many people prescribed CPAP were actually not using it, whereas everyone who had surgery did receive the benefit of surgery. A subanalysis seemed to indicate that regular CPAP users actually had better survival than surgery patients, but again the total group of CPAP patients (including many nonusers) did worse. This sort of population-based outcomes study is very important in determining treatments that actually work in populations. This is also an example of the difference between effectiveness research (in a real-world population) and efficacy research (in a controlled trial).

Meta-analysis is another type of outcomes research. In meta-analysis, the results from several individual studies are combined and a new statistical analysis is performed using the raw data from individual studies. Meta-analysis is more than just a detailed review of the literature, and to perform the analysis, each study must have used very similar methods and report data in a similar format. Despite some methodologic complexity, meta-analysis is a very helpful tool to help achieve an adequate sample power to answer some questions that individual small studies cannot, and also to help resolve conflicting results from individual studies.

EVIDENCE-BASED MEDICINE

Evidence-based medicine (EBM) is an important topic in contemporary medicine. While in fact there is some type of evidence behind many aspects of medical treatment, the explicit techniques of "EBM" have only been recently described and popularized. Dr. David Sackett has been a key developer and leader in EBM and is the lead author on an excellent textbook in the field (10).

More medical schools are teaching their students the techniques of EBM, and articles, books, lectures, and courses on EBM are popular in many fields. Two contemporary disease-related textbooks cover surgical fields: *Evidence-based otitis media*, by Rosenfeld and Bluestone, and *Evidence-based otolaryngology*, by Shin, Hartnick and Randolph.

EBM has been defined as the conscientious, explicit, and judicious use of the current best evidence in making decisions about the care of individual patients (11). Furthermore, the practice of EBM has been described as integrating individual clinical expertise with the best available external clinical evidence from systematic research (11,12). Several points—and misconceptions—are worth emphasizing.

First, EBM does *not* mean only the use of randomized clinical trials. The definition states that it requires the use of the "best available" evidence, not "only the best" evidence. If findings from a randomized clinical trial are available, then that is strong, high-quality evidence and should be used. If, however, randomized trials have not been performed and therefore that type of evidence is not available, you can still practice EBM by using the best available evidence.

Next, EBM does *not* eliminate the physician's own experience or knowledge base. The physician should integrate their own clinical experience with the patient's desire and with the current best clinical evidence when deciding on the best treatment for an individual patient.

The practice of EBM has been likened to a three-legged stool—which would be unstable if one leg were missing (13). The three "legs" of the stool are best evidence, clinical experience, and patient wishes. Along those lines, it would not be practical or reasonable for a physician to rely

only on results from high-quality evidence to make clinical decisions—since there are many questions and issues that have not been addressed with experimental studies. On the other hand, if a physician relies only on personal experience, their practice could become out of date or inappropriate. So the thoughtful and appropriate combination of experience and evidence is a goal to emulate.

There are five steps in practicing EBM (10,12), and we cover each step individually. Those steps are as follows:

1. Ask an answerable clinical question.
2. Search for the best available external evidence.
3. Critically appraise the quality of the evidence.
4. Understand the findings from the best evidence and create a summary/recommendation.
5. Integrate the best evidence with clinical expertise and unique patient factors (desires, values, unique circumstances).

Ask an Answerable Clinical Question

This step might seem simple but in fact can be challenging. Many questions that clinicians might pose are quite general—for example, "is endoscopic sinus surgery effective?"—and there will be limited or no evidence that directly addresses such a question. When developing a specific and answerable question, there are several aspects of the question that should be considered: a helpful tool is to remember "PICO": Patient, Intervention, Comparison, Outcome. Good clinical questions will usually define each of those four components. An example of a good question is the following: "In a 5-year-old child with acute Group A streptococcal pharyngitis (patient), does treatment with antibiotics and anti-inflammatories (intervention) reduce symptoms and fever duration (outcomes), compared to anti-inflammatories alone (comparison)?" That is a potentially answerable clinical question.

While it is *possible* to practice EBM when starting with very general questions, experts in the field have found that focusing the question makes all the subsequent steps easier—particularly the search for evidence.

Search for the Best Available Evidence

The evidence used in EBM is from clinical studies on humans, not from laboratory or animal studies. The evidence search should be a rigorous process for the most contemporary evidence using available technology—not merely identifying a textbook chapter or other handy reference. There are some available databases, for example, the Cochrane Library, that identify and grade pertinent literature on many clinical topics. These are usually compiled by experts, and updated regularly. In addition, there are journals devoted to EBM. Furthermore, evidence-based reviews for many clinical questions have been completed and disseminated. These might be published in the peer-reviewed literature, or as monographs, or placed on Web sites, among other locations. So on occasion, it is possible to identify the best evidence without actually performing the search yourself.

If, however, you need to perform your own search, then using MEDLINE over the internet is another option. This topic is explored in more detail elsewhere (14). But briefly, MEDLINE is a database of the published biomedical literature from around the world. It is maintained by the National Library of Medicine and is available on the internet free of charge. Journal articles are referenced into MEDLINE by trained librarians using index terms called Medical Subject Heading terms, or "MeSH terms." Once the user becomes familiarized with the techniques of searching using MEDLINE, comprehensive lists of articles that cover a particular topic can be identified. The search should be organized and planned to identify articles that address the answerable question.

MEDLINE is quite comprehensive, so in fact, many times a search will yield a very large number of articles—many of which might not be pertinent to the search of interest. In addition, not *all* medical journals are indexed into MEDLINE, and very old articles are not included (although MEDLINE is systematically adding references from before 1966). So there is some published literature that will not be found using MEDLINE. However, MEDLINE is overall an extraordinarily powerful tool for searching the biomedical literature.

Once the search is completed, the list of articles identified should be perused, and articles pertinent to the specific question pulled for further review.

Critically Appraise the Quality of the Evidence

In EBM, there is a fundamental principle at work: not all evidence is equal. Studies are evaluated based on their methodology, and studies using superior methodology are given more "weight" and evidence from those studies is considered more strongly. The basic rules of study quality are as follows: randomized studies are better than nonrandomized, prospective studies are better than retrospective, and controlled studies are better than noncontrolled. By definition, in EBM, only clinical studies using human subjects are considered. While basic laboratory research is an essential part of discovery in medicine, until studies have been performed in humans, their results are not included in the practice of EBM.

Individual studies are rated and given a *level*, based on the quality of the methodology. The standard hierarchy of levels proposed by Sackett is shown in Table 8.2. There are different levels depending on the type of question or study. For example, in a study on active therapy, the best methodology would be a randomized controlled trial (RCT); therefore, that represents level 1 evidence. However, in a study of the prognosis of some disease, randomization is not an option, and the best possible methodology would be a prospective cohort study; therefore, that is level 1 evidence for that type of question.

TABLE 8.2 EVIDENCE LEVELS FOR THERAPY/ETIOLOGY STUDIES AND PROGNOSIS STUDIES

Evidence Level	Therapy/Etiology	Prognosis
1a	Systematic review (SR) of RCTs	SR of inception cohort studies
1b	Single RCT	Individual cohort study
1c	"All or none" study	"All or none" case series
2a	SR of cohort studies	SR of either retrospective cohort studies or untreated control groups in randomized trials
2b	Individual cohort study	Retrospective cohort studies or untreated control groups in randomized trials
2c	Outcomes research	Outcomes research
3a	SR of case–control studies	
3b	Individual case–control study	
4	Case series	Case series
5	Expert opinion	Expert opinion

Modified Sackett DL, Straus SE, et al. *Evidence-based medicine: how to practice and teach EBM*, 2nd ed. London: Wolfe Pub Ltd., 2000, used with permission.

Study ratings are based on methodology, but if there are other problems with the study, the reviewer has options. If the study has major flaws, such an inappropriate entry criteria or obvious bias, the reviewer may exclude the study and not give it any grade. If problems are more minor, such as no power analysis or incomplete data reporting, then the study can be given a "minus" grade, such as level 2–. It is not appropriate to move the evidence level down a level, such as from 2 to 3, because a different level of evidence means a different methodology was used.

Studies should be organized, from highest level to lowest. Often, creating a table is the best way to organize the studies. If there are multiple studies of the same level, then studies showing similar findings can be organized together.

With the effort involved in creating a question, searching, finding, and grading the literature, it may be wise to maintain a record of search results, particularly for frequently asked questions. These organized search results have been called critically appraised topics, or "CATs" (10). When practicing EBM, the clinician can refer back to CATs whenever needed, and when new evidence is reported, it can be added to an existing CAT.

Understand the Results and Create a Recommendation

Once individual studies have been rated, then the overall results and findings are reviewed for evidence quality and the consistency of results. While individual studies are given *levels*, the overall evidence is given a *grade*. Grades of evidence are summarized in Table 8.3. This final compilation can be called a grade of recommendation or grade of overall evidence.

There is some judgment required in assigning a grade to the overall evidence. The grade is based on the best quality evidence, and the consistency of evidence and results—not just the level of evidence with the most papers. For example, there will often be multiple case series (level 4 evidence) reported, but if there are a large number of RCTs with consistent results, that would considered grade A evidence—even if there are numerically more level 4 studies than level 1. On the other hand, just because there are one or two RCTs (level 1 studies), that does not automatically mean there is grade A evidence. If the few studies show conflicting results or have methodologic problems, and the rest of the studies are case series, then the overall evidence might actually be grade C. Again, this requires some interpretation and judgment by the reviewer.

Integrate Best Evidence with Clinical Experience and Patient's Circumstances

This is the key last step in practicing EBM. After the best external evidence has been identified, graded and summarized, and an overall grade of recommendation created, that recommendation is then integrated with the patient's unique circumstances and the clinician's experience and judgment. The physician practicing EBM should keep in mind the "three legs" of EBM and the importance of each.

TABLE 8.3 GRADES OF OVERALL EVIDENCE

Evidence Grade	Levels of Evidence
Grade A	Consistent level 1 studies
Grade B	Consistent level 2 or 3 studies
Grade C	Level 4 studies
Grade D	Level 5 studies

Modified from Sackett DL, Straus SE, et al. *Evidence-based medicine: how to practice and teach EBM*, 2nd ed. London: Wolfe Pub Ltd., 2000, used with permission.

Evidence-Based Medicine Summary

The techniques of EBM are useful in identifying the best care for an unusual disease or condition, as well as for summarizing and incorporating the results from contemporary research into routine treatment of common disorders. EBM allows for clinical experience and for innovation, but stresses rigor and the scientific method in identifying the best treatment for each patient.

EVIDENCE-BASED GUIDELINES

Evidence-based guidelines are a product of EBM, where treatment recommendations are formulated into guidelines for the practitioner—with recommendations given different strength, based on the quality of the underlying evidence (15,16). The development of consensus evidence-based guidelines is a detailed and lengthy process, which often requires external funding and significant time contribution by experts. In many diseases, inclusion of content and clinical specialists from multiple disciplines is recommended to ensure that all evidence is included and reviewed with minimal bias. For example, an early guideline developed in otitis media with effusion included pediatricians, otolaryngologists, and audiologists in the review panels. The American Academy of Otolaryngology–Head and Neck Surgery Foundation has undertaken the development of multiple evidence-based guidelines and has detailed the steps involved in guideline development in a comprehensive and helpful publication (16). The Academy Foundation completes each guideline over several months.

The Cochrane Collaboration also reports evidence-based reviews, again using a rigorous iterative process of literature retrieval and review, with recommendations made based on the strength of evidence (17). There are Cochrane working groups in most specialties including Otolaryngology, and that group has published a variety of reviews. Cochrane groups generally take the view that they will only perform a review or create a guideline when there is sufficient level 1 evidence on the question. Their view is "top down" in that they start with only the best evidence, and therefore, they will not expend the time and energy to create a guideline if the best evidence happens to be low-level.

Some articles are also reported as "evidence-based reviews" or reports because they use the same steps in identification, review, and compilation of evidence but without the large panel and multiple iterations. In some cases, particularly when the question is straightforward and the evidence is manageable, these published reviews will likely be equivalent to a more formal one developed using the more extensive process.

Guidelines are organized around statements of action, for example, what a clinician should do or what test they should perform. These actions are given different levels of recommendation, depending on the strength of the underlying evidence and also the probability of benefit or harm associated with a treatment or test. The "final product" of the evidence review is a *recommendation*, which is given one of the following levels: Strong Recommendation, Recommendation, Option, or No Recommendation.

These levels can be summarized as follows (16). "Strong recommendation" means the benefits clearly exceed the harms, and the supporting evidence is strong. Therefore, clinicians should follow this recommendation, unless there is strong reason not to. "Recommendation" means that the benefits exceed the harms, although the evidence is not as strong, and clinicians should generally follow this recommendation, subject to additional information or patient preference. "Option" means that either the evidence is not strong or that strong evidence shows conflicting results, and in this case, clinicians have flexibility in treatment decisions, and patient preference can play a more significant role. "No recommendation" means that supporting evidence and benefit/risk data are insufficient to allow any recommendation to be made.

The organization of potential recommendations is shown in Table 8.4, but in the process of making a guideline

TABLE 8.4 RECOMMENDATIONS USED IN PRACTICE GUIDELINES

Evidence Grade	Levels of Evidence	Preponderance of Benefit or Harm	Balance of Benefit or Harm
Grade A	Consistent level 1 studies	Strong recommendation	Option
Grade B	Consistent level 2 or 3 studies	Strong recommendation or recommendation	Option
Grade C	Level 4 studies	Recommendation	Option
Grade D	Level 5 studies	Option	No recommendation
Grade X	Exceptional situation: no studies, but clear evidence of benefit or harm	Strong recommendation or recommendation	

Adapted from Rosenfeld RM, Shiffman RN. Clinical practice guidelines: a manual for developing evidence-based guidelines to facilitate performance measurement and quality improvement. *Otolaryngol Head Neck Surg* 2006;135(4 Suppl):S1–S28.

recommendation, the lines between levels of recommendation are not always absolute. However, you would usually not make a strong recommendation if the best evidence was grade C, for example.

So in summary, evidence-based guidelines are an extension of EBM, where the best evidence is systematically reviewed by a multidisciplinary panel of experts and treatment decisions are organized into a series of recommendations to guide the clinician during treatment. These are recommendations and should always be balanced with clinical experience, and potential unique circumstances of a particular patient.

HIGHLIGHTS

- Outcomes research can be divided into patient-based research and record-based research.
- Patient-based outcomes research is characterized by the assessment of expanded measures of outcome, such as quality of life and patient-based disease-specific health status, as well as new research methodologies such as observational studies.
- The steps in patient-based outcomes research are as follows: identify and define the disease of interest, create a disease severity staging system, identify comorbid conditions, and establish the outcomes to be measured.
- There are multiple available validated instruments to assess global and disease-specific quality of life.
- Patient-based outcome studies in otolaryngology have demonstrated the effectiveness of many common surgical treatments.
- Some examples of record-based outcomes research are appropriateness research and population studies.
- EBM can be defined as the conscientious, explicit, and judicious use of the current best evidence in making decisions about the care of individual patients.
- In the practice of EBM, there are five steps: ask an answerable clinical question, search for the best available external evidence, critically appraise the quality of the evidence, understand the findings and create a summary/recommendation, and integrate the best evidence with clinical expertise and unique patient factors.

Introduction to Otolaryngic Genetics

9

Selena E. Heman-Ackah *Anil K. Lalwani*

Human genetics forms the foundation of existence and the backbone of basic human formation and function. Since the turn of the century, the body of knowledge and understanding of human genetics has grown tremendously. The decoding of the human genome has unlocked the door to understanding gene function. Further investigation and unveiling of the genetic code will facilitate the identification of fundamental genes, critical genetic pathways, and deleterious genetic disorders. Current studies are now aiming to decipher the complex interaction between environmental factors and genetics in the manifestation and evolution of genetic disorders. As the body of knowledge continues to grow, human genetics will increasingly be an integral component in the diagnosis, prevention, and ultimately treatment of genetic disorders. This will further aid in identifying disease susceptibility to treatments and targeted therapies to improve individualized drug response. The utilization of genetics in diagnosis and treatment planning may dramatically revolutionize the management of chronic diseases that have plagued mankind for centuries.

Consequently, a keen understanding of human genetics, both the current triumphs and future endeavors, is essential to the practice of otolaryngology—head and neck surgery. Numerous genetic disorders are encountered in otolaryngology and its subspecialties. These genetic disorders may occur as a result of sporadic chromosomal anomalies and mutations or may be transmitted from generation to generation. The purpose of this chapter is to review the basic principles of human genetics and to review genetics as it pertains to the practice of otolaryngology. This chapter provides an overview of normal human genetics, patterns of genetic transmission, genetic disorders in otolaryngology, and molecular therapies in genetics.

MOLECULAR BASIS OF INHERITANCE

The human genetic code provides the basis upon which information encoded within genetic material is translated into proteins vital to cellular function and the sustenance of life. This process starts with deoxyribonucleic acid (DNA), which is transcribed as ribonucleic acid (RNA) and ultimately translated into proteins and polypeptides (Fig. 9.1). This is a highly specific and regulated process by which the building blocks of life are created.

DNA and Chromosomes

DNA provides the basis for all genetic material and is the cornerstone of the human genomic code. DNA provides the code from which all human proteins are derived. The majority of DNA is housed within the cell's nucleus with a relative minor proportion being contained within the mitochondria. Nuclear DNA is referred to as autosomal DNA, whereas DNA derived from the mitochondria is referred to as mitochondrial DNA. Roughly half of all autosomal DNA is derived from each parent respectively. All mitochondrial DNA is maternally derived. The structure of autosomal and mitochondrial DNA differs substantially.

DNA is a double-stranded helix comprised of two paired nucleotides with a phosphate-deoxyribose backbone joined by ester bonds. Within DNA, there are four nucleotides with specific binding patterns: adenine (A) pairs with thymine (T) and cytosine (C) pairs with guanine (G). The entire human autosomal DNA genome is comprised of 3×10^9 base pairs measuring approximately 2 m in length, all of which is condensed and housed within a nucleus that is only 0.06 μm in diameter. Less than 5% of the entire human genome codes for the fewer than 30,000 genes that are translated into proteins. A trinucleotide sequence,

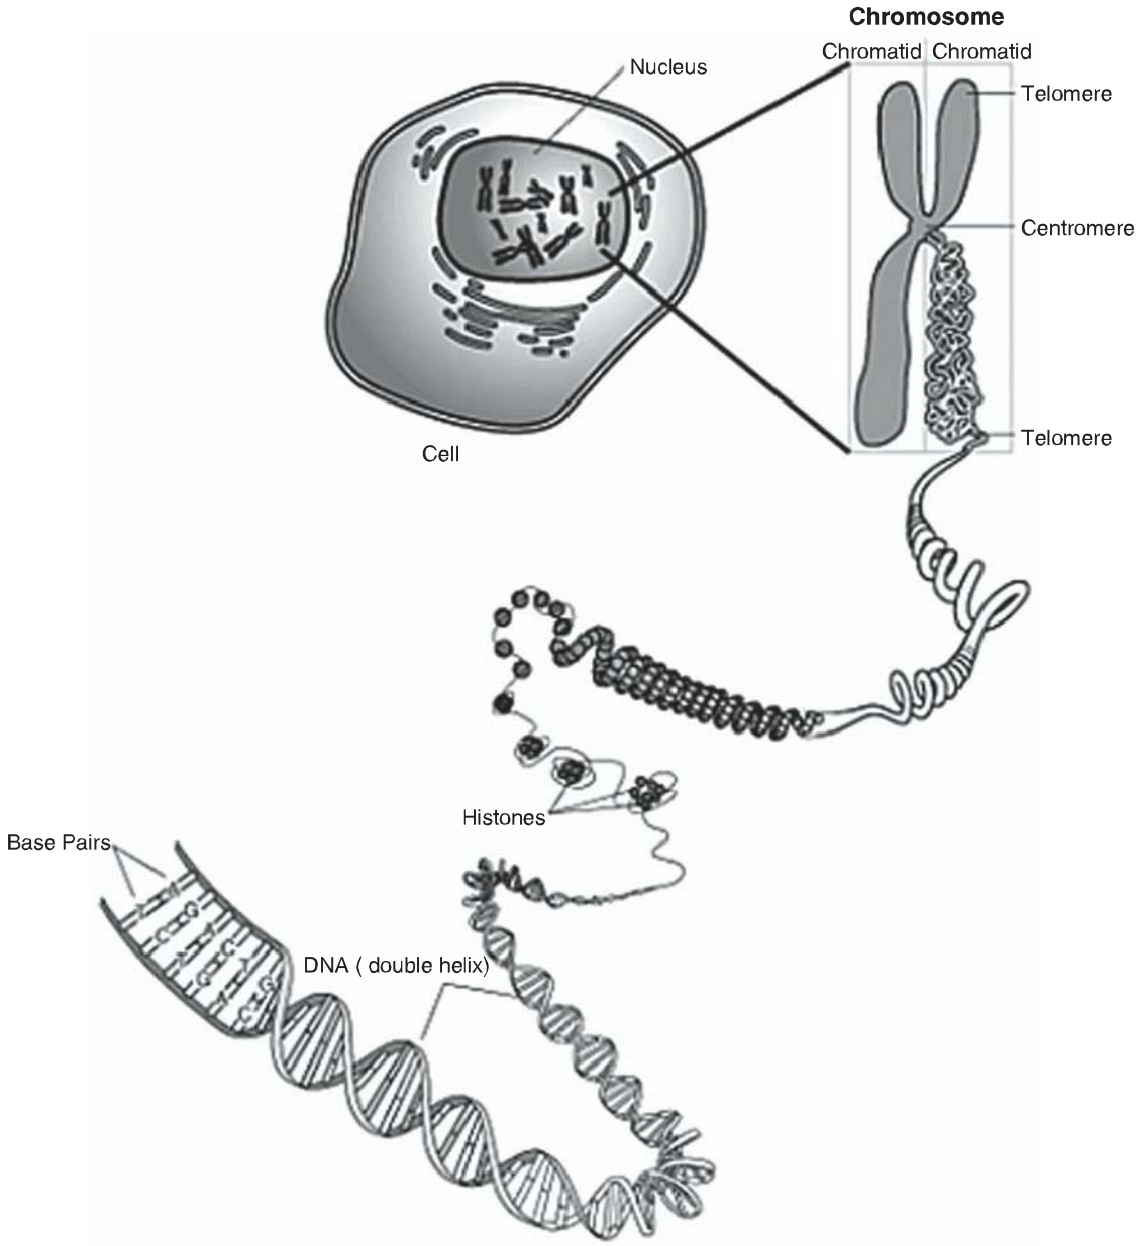

Figure 9.1 Structure and components of the chromosome.

a codon, corresponds to a specific amino acid. Each DNA molecule is comprised of a sense or coding strand (5′ to 3′) that is paired with a complementary antisense or template strand (3′ to 5′). Segments of the DNA containing genetic information that is transcribed into corresponding RNA, proteins, and polypeptides are called genes.

Within the nucleus, DNA is organized into chromosomes following DNA replication and preceding cellular division. Chromosomes are comprised of dense DNA-protein complexes known as chromatin. The human genome contains 23 paired chromosomes of maternal and paternal origin for a total of 46 chromosomes: female (46, XX) and male (46, XY) (Fig. 9.2).

Mitochondrial DNA is also comprised of a double-stranded helix. However, instead of the linear organization, mitochondrial DNA is a circular molecule with 16,569 base pairs (Fig. 9.3). Each mitochondrion contains multiple copies—from 100 to 10,000—of this circular DNA (1). The mitochondrial genome consists of 37 genes coding for 2 rRNAs, 22 tRNAs, and 13 polypeptides. Mitochondrial DNA is essential in its contribution to enzyme complexes critical for oxidative phosphorylation (2). During fertilization, the nucleus of the sperm and oocyte fuse, allowing for transmission of both maternal and paternal autosomal DNA into the developing offspring. Interestingly, shortly following fertilization, the mitochondria derived from the

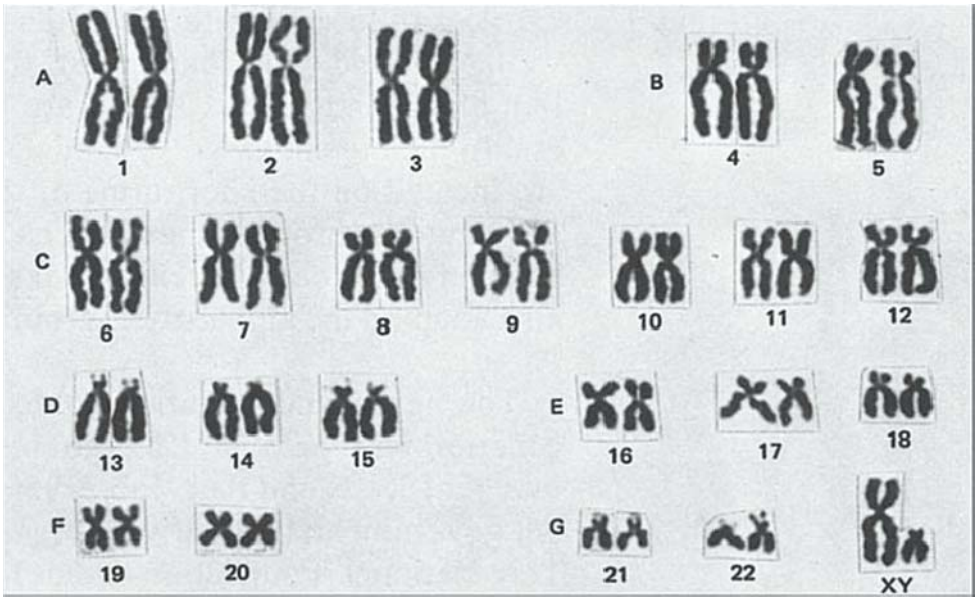

Figure 9.2 Human karyotype.

sperm undergo programmed destruction, leaving only the maternally mitochondria within the developing offspring (3). For this reason, mitochondrial DNA is solely of maternal origin.

RNA and Proteins

Information coded within the genome is translated into the vital proteins by RNAs. Similar to DNA, RNA is comprised of a sugar-phosphate backbone with a nucleotide base. However, unlike the double-stranded configuration of the DNA molecule, RNA is configured as a single-stranded molecule. RNA is comprised of three of the same nucleotide base pairs encountered in DNA: adenine (A), guanine (G), and cytosine (C). The thymine (T) base associated with DNA is replaced by uracil (U) in the RNA molecule. Similarly, during the transcription process, adenine pairs with guanine, and uracil replaces thymine in pairing with cytosine. There are multiple types of RNA, which are critical to the cellular function (Table 9.1).

RNA functions to aid in the transcription of the DNA code and the translation of the genetic code into protein

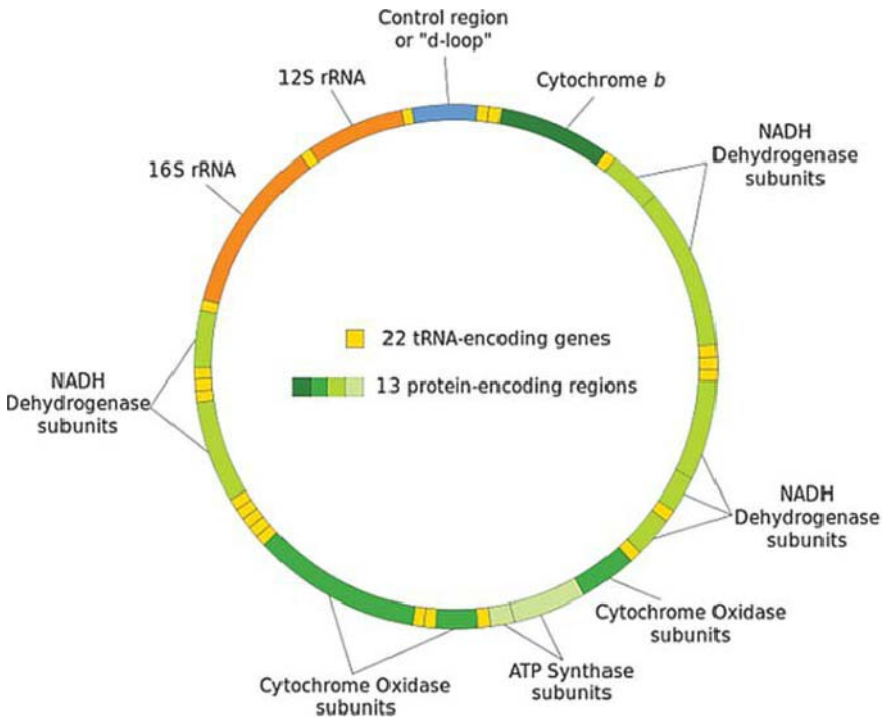

Figure 9.3 The mitochondrial genome.

TABLE 9.1 TYPES OF RIBONUCLEIC ACIDS

Types of RNA	Abbreviation	Function
Messenger RNA	mRNA	Codes for protein sequence Essential to transcription
Micro RNA	miRNA	Posttranscriptional regulators Translational repression and gene silencing
Ribosomal RNA	rRNA	Decoding mRNA Interact with tRNA during translation
Small interfering RNA (inhibitory RNA, silencing RNA, short interfering RNA)	siRNA	Interferes with specific gene expression Antiviral mechanism Shaping chromatin structure of the genome
Small nuclear RNA	snRNA	RNA splicing Regulation of transcription factors Maintenance of telomeres
Signal recognition particle RNA	SRP RNA	Translational translocation Membrane integration Posttranslational transport
Transfer RNA	tRNA	Translation

and polypeptide products (Fig. 9.4). In short, during the process of transcription, messenger RNA (mRNA) pairs with DNA, utilizing the sense strand as a template. Therefore, mRNA is configured in a 3′ to 5′ orientation and is identical to the antisense strand of DNA with the exception of the thymine to uracil substitutions. Transcription takes place completely within the cell nucleus. Once this process is complete, the mRNA exits the nucleus where, with the assistance of transfer RNA (tRNA) and ribosomal RNA (rRNA), the code is translated on a ribosome (a complex of protein and rRNA) into protein. Because the mRNA is similar to the antisense DNA strand, the nucleotide bases of the tRNA correspond directly to that of the sense DNA strand. For translation to occur, tRNAs specific for individual amino acid, with the amino acid covalently attached to it, are required. Each nucleotide triplet represents a codon, of which there are 64, corresponding to a specific amino acid or a stop signal (Fig. 9.5). The peptide produced by the tRNA ultimately forms proteins and polypeptides, which are critical to virtually every cellular function.

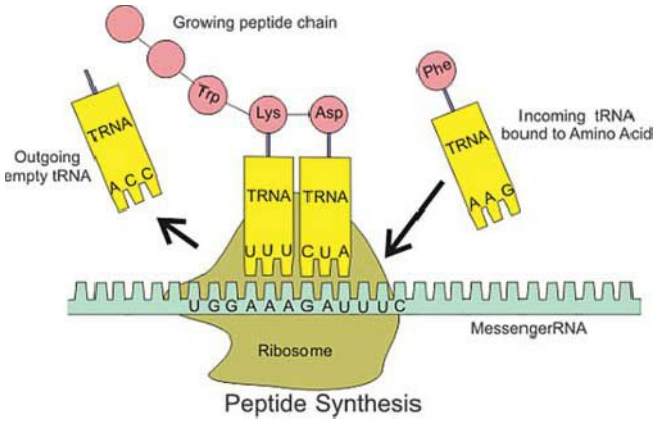

Figure 9.4 RNA translation.

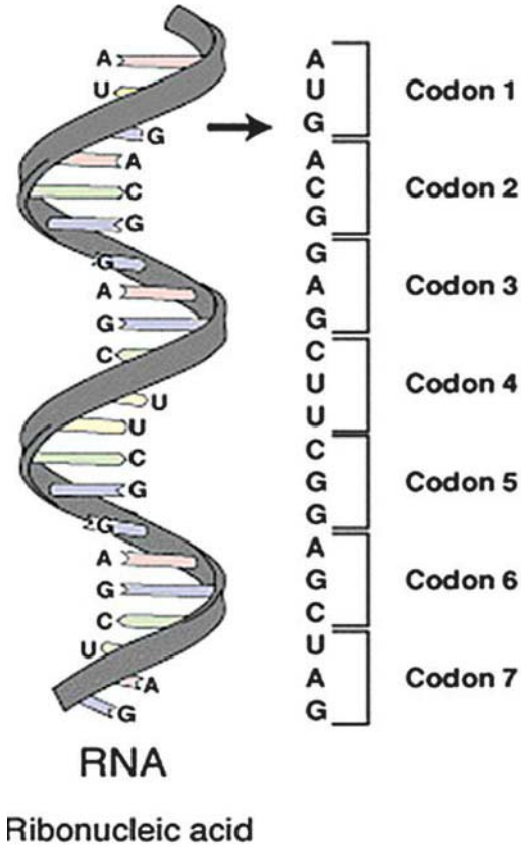

Figure 9.5 Nucleotide triplets.

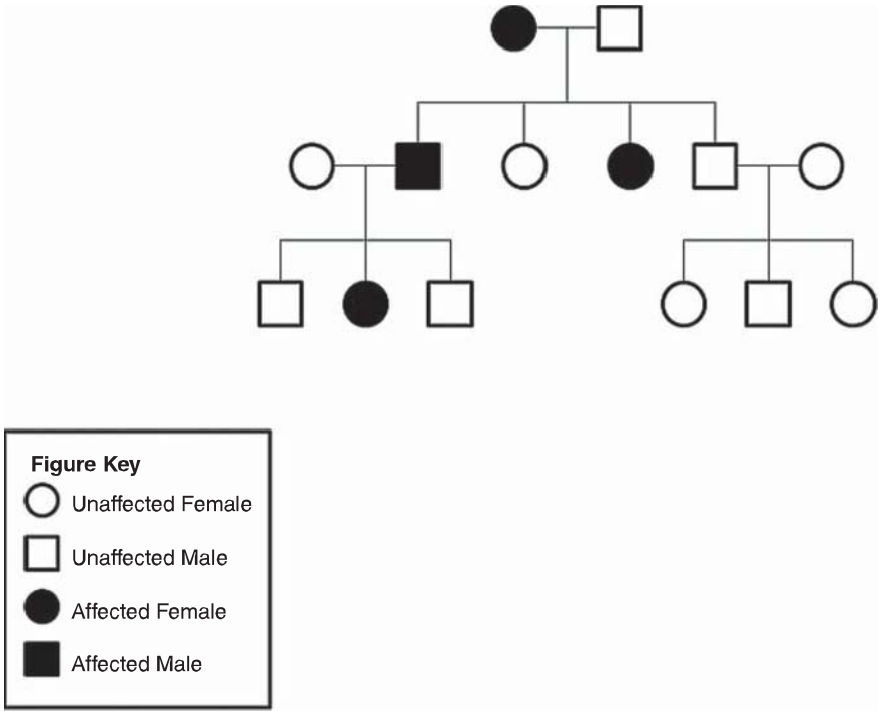
Proteins are essential for cellular structure and life function. Proteins form the structural components of cells, the foundational material of tissue, and the enzymes that catalyze chemical reactions. Although every cell contains the entire genome, only specific genes are expressed to enable the production of the precise proteins required for that specific cell's function. The entire process of gene expression to protein production, therefore, requires precise timing and orderly expression of genes specific to carry out functions within divergent cells and organ systems.

MENDELIAN GENETICS

The concepts of Mendelian genetics were first introduced by Gregor Mendel in his work *Experiments in Plant Hybridization* in 1865 presented on February 8 and March 8 before the *Naturforschender Verein* (Natural Science Association) in Brunn (4,5). Using the pea plant for artificial insemination studies, he was able to identify various patterns of inheritance based upon transmission of specific physical characteristics in the plant's offspring such as color variations and seed form. The works of Mendel were largely ignored for a period of 35 years until their rediscovery in 1900 independently by Correns et al. (6). Since then, Mendel's model of inheritance has become the cornerstone of human genetics. The main forms of Mendelian inheritance include autosomal dominant, autosomal recessive, and sex-linked inheritance, all of which are discussed in detail below. Table 9.2 provides definitions of basic terminology upon which Mendelian genetics is based.

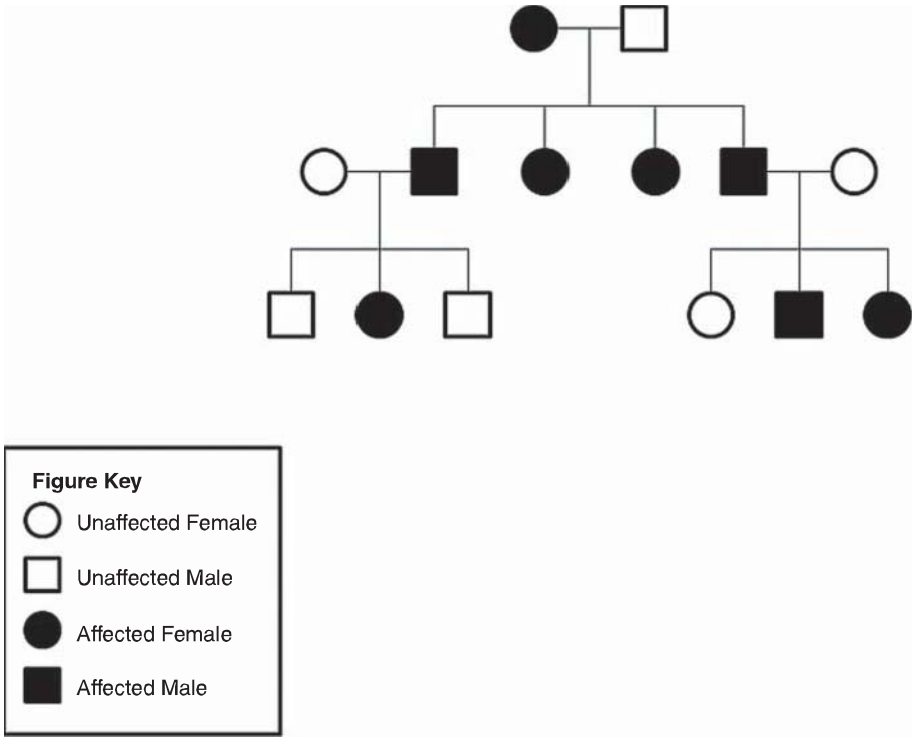
Autosomal Dominant Inheritance

Each individual possesses two copies or alleles of a specific gene, one maternally derived and the other paternally derived. Autosomal dominant inheritance is a form of inheritance wherein only a single mutated allele is required for the transmission of disease. Therefore, an individual with the disease phenotype need only inherit the mutated allele from one parent while inheriting a normal allele from the other parent. Figure 9.6 depicts a prototypical pedigree of a family with autosomal dominant inheritance. If one parent possesses one diseased allele (heterozygous dominant) and the other parent possesses two normal alleles, their offspring have a 50% chance of inheriting the disorder. Alternatively, in extremely rare cases, if one parent possesses two diseased alleles (homozygous dominant) and the other parent possess two normal alleles, the offspring have a 100% chance of inheriting the disorder. There is no sexual predilection in the pattern of inheritance with autosomal dominant disorders. Additionally, there is no carrier state with autosomal dominant disorders. Therefore, inheritance of one disease allele confers the phenotype of disease unless there is "incomplete penetrance." Inherited diseases may demonstrate complete penetrance (every individual with the disease allele has the disease phenotype) or incomplete penetrance (not all individuals with the disease allele have the disease phenotype). Because of the nature of transmission, autosomal dominant disorders are rarely associated with fatal mutations. This is because the presentation of fatal mutations with autosomal dominant inheritance would preclude its transmission.



There are a number disease in otolaryngology with known autosomal dominant inheritance including achondroplasia, Charcot-Marie-Tooth, Ehlers-Danlos syndrome, Marfan syndrome, neurofibromatosis type I, neurofibromatosis type II, osteogenesis imperfecta, Pfeiffer syndrome, von Hippel-Lindau syndrome, Treacher-Collins syndrome, Noonan syndrome, Osler-Weber-Rendu syndrome, Gorlin syndrome, branchio-oto-renal (BOR) syndrome, DiGeorge syndrome, Gardner syndrome, Pallister-Hall syndrome, Stickler syndrome, van der Woude syndrome, and otosclerosis. These disorders are discussed later in the chapter.

TABLE 9.2 BASIC GENETIC TERMINOLOGY



Terminology	Definition
Genotype	Genetic constitution of a particular genetic locus
Phenotype	Observable characteristics of a cell or organism that are coded by a particular genetic locus
Alleles	The particular form of a gene on each chromosome
Homozygous	Individual who carries two identical alleles of a specific gene loci
Heterozygous	Individual who carries two different alleles of a specific gene loci

Autosomal Recessive Inheritance

With autosomal recessive inheritance, two diseased alleles are required for the phenotypical presentation of disease. Figure 9.7 depicts a prototypical pedigree of a family with cystic fibrosis, an autosomal recessive disorder. Cystic fibrosis is caused by various mutations within the CFTR gene (7). If an individual possesses two mutated CFTR genes (homozygous recessive), they phenotypically present with cystic fibrosis. However, if an individual possesses only one mutated CFTR gene and possesses one normal copy (heterozygous recessive), this individual is considered a carrier. Carriers typically do not phenotypically present with the disease process, but possess the ability to pass the abnormal gene to their offspring. If two carriers procreate, 25% of their offspring will have the disease process (homozygous recessive), 25% of their offspring will have two normal alleles, and 50% of their offspring will be carriers (heterozygous recessive). Additionally, if one parent is a carrier and one parent is normal, half of their children will be carriers and half will be normal.

A

B

Figure 9.6 **A**: Pedigree of family with neurofibromatosis (heterozygous dominant parent inheritance). **B**: Pedigree of family with neurofibromatosis (homozygous dominant parent inheritance).

Like autosomal dominant disorders, there are numerous examples of autosomal recessive diseases within otolaryngology. These disorders include Usher syndrome, Refsum disease, Pendred syndrome, Jervell Lange-Nielsen syndrome, xeroderma pigmentosa, Fanconi anemia, Friedreich ataxia, and Letterer-Siwe disease. Unlike autosomal dominant disorders, genetic disorders with lethal phenotypes are more likely to be autosomal recessive in

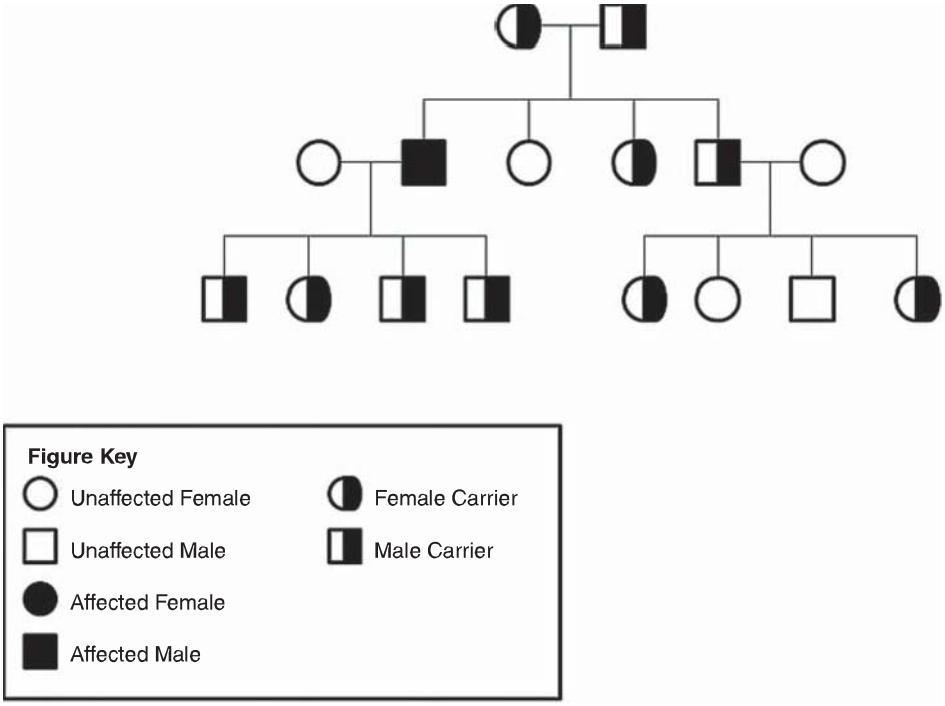


Figure 9.7 Pedigree of family with cystic fibrosis (autosomal recessive inheritance).

nature owing to the normal phenotypical presentation of the carrier individuals at childbearing age. Autosomal recessive disorders with lethal phenotypes, such as Tay-Sachs disease and Bowen-Conradi syndrome, most often occur in patient with no prior family history of disease. The lethal phenotypes tend to occur more frequently among consanguineous families in which the parents are genetically related. Many autosomal recessive disorders tend to have a racial or ethnic predilection (i.e., sickle cell anemia, β-thalassemia, and Gaucher disease) believed to be a function of the founder effect. The founder effect describes the expression of a mutation initially occurring in one or few founding members of a group that has been propagated by the tendency for marriages to occur within the same group. As with autosomal dominant disorders, there is no sexual predilection associated with autosomal recessive disorders.

Sex-Linked Inheritance

Sex-linked inheritance refers to genes expressed on the X or Y chromosome. Among humans, most sex-linked genetic disorders are carried on the X chromosome. As the daughter inherits an X chromosome from the mother and the father, therefore, with X-linked disorders, a female may inherit a mutated gene allele from either the mother or the father. However, as the male inherits the X chromosome from the mother and the Y chromosome from the father, thus, sons can only inherit the diseased allele from the mother. X-linked disorders are further subdivided into X-linked dominant and X-linked recessive disorders.

X-linked dominant disorders are exceedingly rare. As with autosomal dominant disorder, X-linked dominant disorders only require one diseased allele for the phenotypical expression of disease. Therefore, both males and females may be affected. Figure 9.8 depicts a pedigree of a family with Aicardi syndrome, an X-linked dominant disorder characterized by partial or complete absence of the corpus callosum, retinal abnormalities, and seizures (8). All females born to a male with an X-linked dominant disorder will possess the disease mutation and express the disease phenotype as the father has only the single affected X chromosome. Paternal possession of X-linked dominant disorders has no influence on the genotype or phenotype of male offspring as the father only passes the Y chromosome to the son. Half of males born to a female with an X-linked dominant disorder will inherit the disease genotype and phenotype. In certain X-linked dominant disorders (i.e., focal dermal hypoplasia), expression of the genetic mutation within males is highly or uniformly fatal. There are few examples of X-linked dominant disorders including X-linked hypophosphatemia, CHILD syndrome, Lujan-Fryns syndrome, and incontinentia pigmenti.

The vast majority of X-linked disorders are recessive in nature, meaning that one functional form of the gene precludes the phenotypical presentation of disease. Figure 9.9 depicts a pedigree of a family with Kallmann syndrome, an X-linked disorder. With X-linked recessive disorders, females possessing one copy of the disease allele are carriers and typically do not have the disease. Females must possess two copies of the diseased allele for expression of disease, which is extremely uncommon. Females may inherit this diseased X-linked allele from either or both parents. However, because male offspring inherit their only X chromosome from their mother, males may only

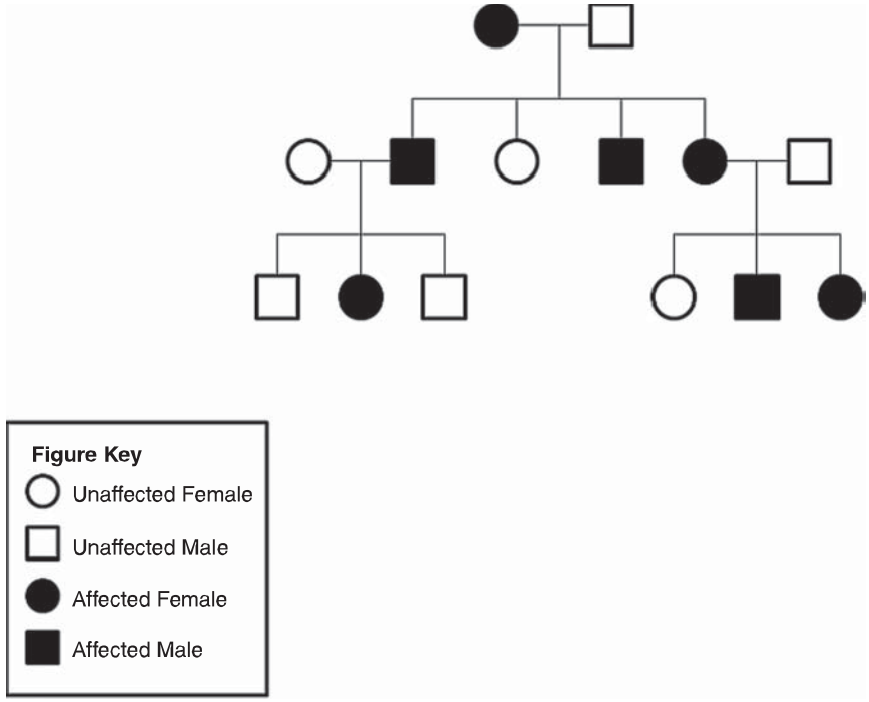

Figure 9.8 Pedigree of family with Aicardi syndrome (X-linked dominant inheritance).

inherit X-linked recessive disorders from their mother. Also, because males lack a second X chromosome, the disease allele represents the only functional X chromosome allele leading to the phenotypical expression of disease. There are a number of X-linked recessive diseases encountered in otolaryngology including X-linked stapes gusher syndrome, X-linked Alport syndrome, idiopathic hypoparathyroidism, X-linked agammaglobulinemia of Bruton, Lesch-Nyhan syndrome, severe combined immunodeficiency disease, Wiskott-Aldrich syndrome, Norrie disease, X-linked ichthyosis, Keipert syndrome (nasodigitoacoustic syndrome), and fragile X syndrome.

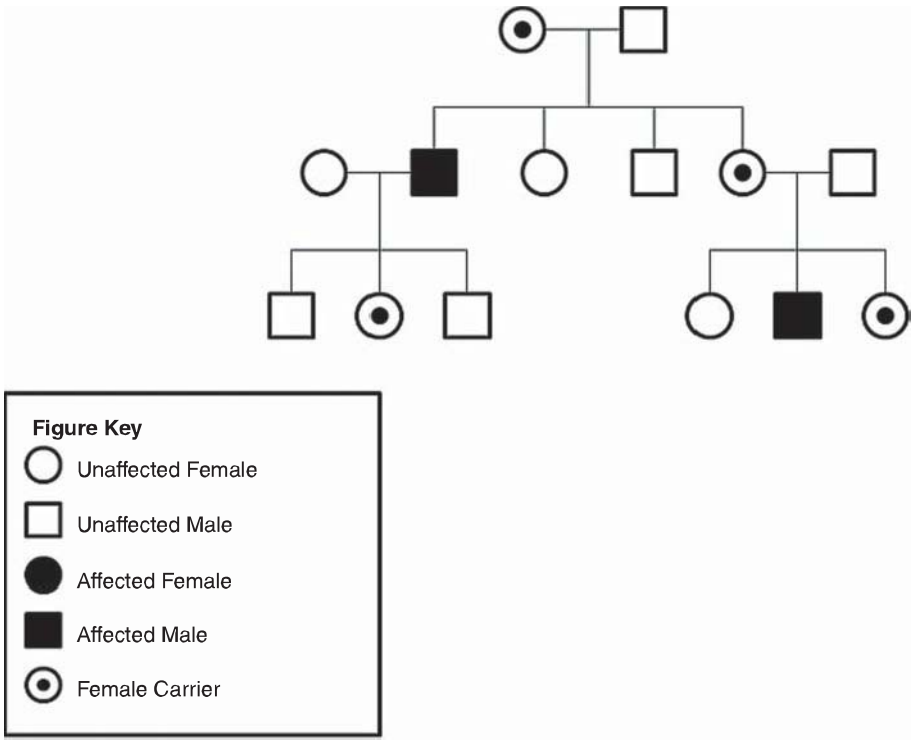

Figure 9.9 Pedigree of family with Kallmann syndrome (X-linked recessive inheritance).

Penetrance and Expressivity

When discussing Mendelian genetics, it is also important to understand the concepts of penetrance and expressivity. Penetrance describes whether individuals carrying a particular gene mutation also express an associated trait or phenotype. Penetrance may be complete or incomplete, that is, among individuals harboring a mutated gene, all or some have the disease, respectively. Expressivity describes the variation in phenotype among individuals carrying a particular genotype. For example, a mutation may be associated five different findings; in patients with a disease characterized by variable expression, they may have one to all five of the features.

Neurofibromatosis type I (NF1), an autosomal dominant disorder, is an excellent example to illustrate the concepts of penetrance and expressivity as it is a genetic disorder characterized by incomplete penetrance with variable expressivity. Individuals with the NF1 genotype may phenotypically appear normal representing the phenomenon of nonpenetrance. Nonpenetrance describes the lack of phenotypical presentation of a genetic disorder in an individual known to possess the genotype associated with disease. Additionally, the expression of NF1 varies greatly among affected individuals. Approximately, 97% of patients with the NF1 genotype have five or more café-au-lait spots, 60% cutaneous neurofibromas by age 20 years, 17% scoliosis, and 13% optic gliomas. The variability in presentation of these components of the disease process is a reflection of the variable expressivity associated with NF1.

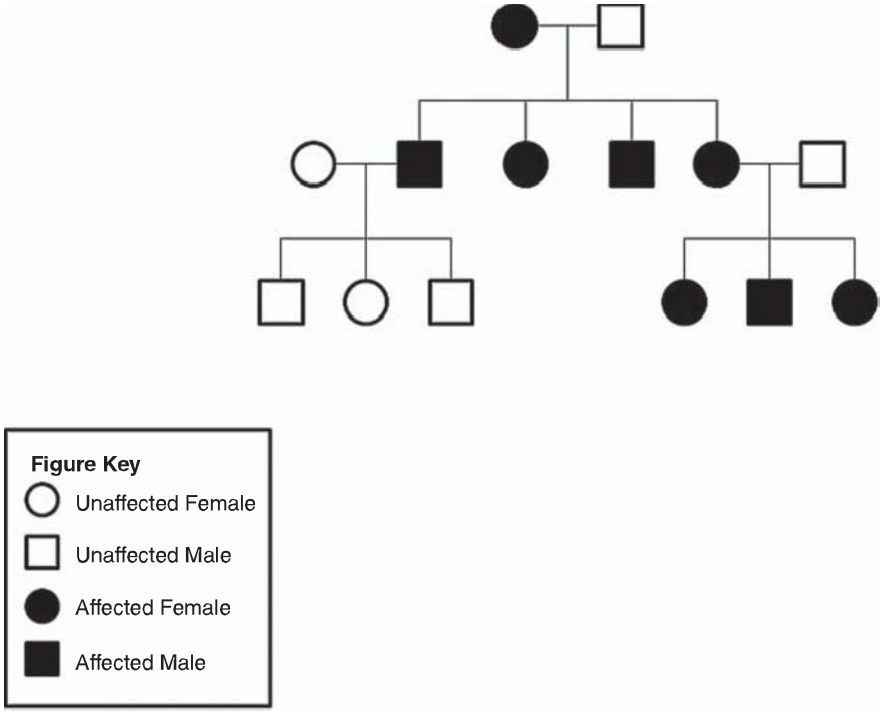
NON-MENDELIAN GENETICS

Mendel's description of patterns of inheritance formed the foundation upon which the current level of knowledge and understanding of genetics was built. In addition to the Mendelian forms of genetic inheritance, further investigation has revealed a number of non-Mendelian processes by which genetic mutations can be inherited conferring the phenotype of a disease. These include mitochondrial inheritance, genetic imprinting, epigenetic influences, digenic inheritance, complex genetics, and chromosomal anomalies.

Mitochondrial Inheritance and Mutations

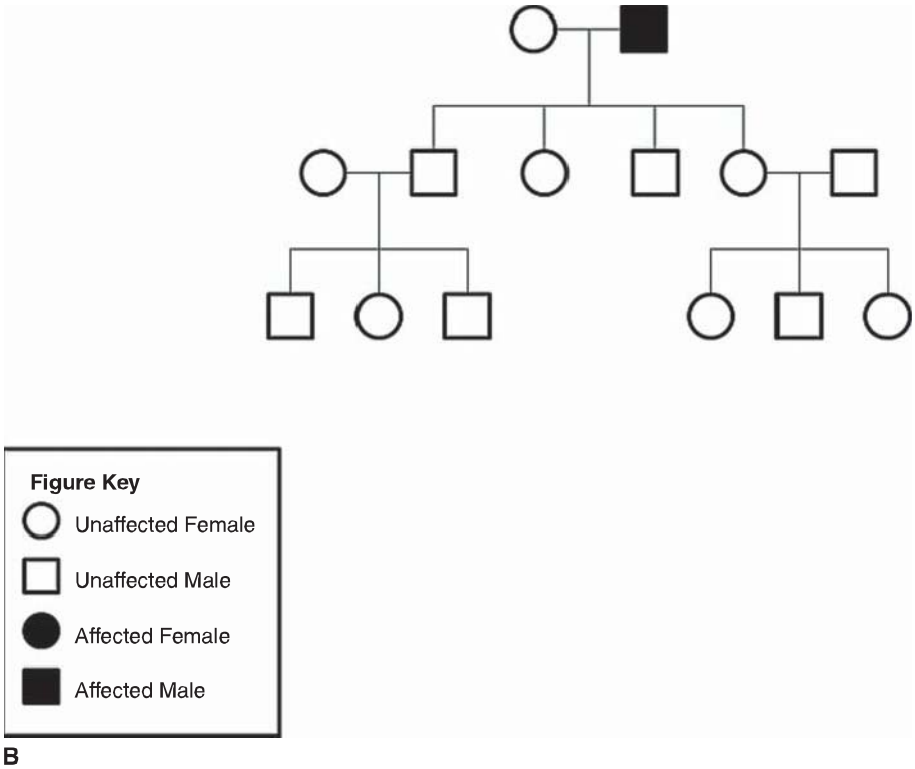
As described above, mitochondrial DNA is instrumental in the production of proteins and enzymes fundamental to oxidative phosphorylation. Mitochondrial DNA is solely maternally inherited. As with autosomal DNA, mutations within the mitochondrial genome can produce the phenotype of disease. These mutations may be inherited or acquired.

Because the mitochondrial genome in maternally transmitted, all inherited mitochondrial genetic disorders are maternally derived (9). Figure 9.10 depicts two pedigrees of families with mitochondrially inherited nonsyndromic hearing loss (MINSHL). The first family depicts the case of a family derived from the maternal unit with MINSHL, and the second depicts the case of a family derived from the paternal unit with MINSHL. Mitochondrially inherited disorders are more rarely encountered in otolaryngology than autosomal inherited disorders and range in severity from asymptomatic to fatal. Because the mitochondrial genome is essential to cellular energy production, tissues with high energy demand are preferentially affected including the nervous system, muscle, heart, and endocrine systems (10). Examples of mitochondrially inherited genetic disorders include aminoglycoside induce ototoxicity, NARP (neuropathy, ataxia, and retinitis pigmentosa), Leber hereditary neuropathy, MELAS (mitochondrial encephalomyopathy, lactic acidosis, and stroke-like episodes), and MINSHL. Certain forms of male infertility are also proposed to be secondary to inherited mitochondrial genomic mutations.



Mutations within the mitochondrial genome may also be acquired. Acquired mitochondrial mutations are proposed to be associated with aging in many organ systems including the inner ear, skin, and retina. Oxidative damage due to increased reactive oxygen species and a decrease in endogenous antioxidants has been identified as a major contributor to acquired mitochondrial genomic mutations (11,12).

Various cancers have also been associated with mitochondrial genomic mutations. These mutations have been found to be germline related and *de novo*. In addition to head and neck tumors, renal adenocarcinoma, colon cancer, astrocytic tumors, thyroid tumors, breast tumors, and prostate tumors have been associated with mitochondrial genomic mutations (13,14).



Genetic Imprinting

Genetic or genomic imprinting is an epigenetic process not described or explained by the traditional Mendelian patterns of inheritance. It describes a genetic process by which certain genes are expressed in a parent-of-origin specific manner. The process of genetic imprinting silences an allele derived from a specific parent such that only the genes from the nonimprinted allele are expressed. Imprinting may occur on either the maternally derived or paternally derived allele. Genetic imprinting is accomplished via methylation of cytosine within DNA and histone acetylation, which produces monoallelic gene expression without alteration of the genetic sequence. The markers for genetic imprinting are established through the germline and are maintained throughout all somatic cells. Imprinted genes are typically grouped within clusters, which allow them to share common regulatory units including noncoding RNA and differentially methylated regions, which together comprise the imprinting control regions (15).

There are a number of genes that have been identified that lead the disease phenotype as a function of genetic

A

B

Figure 9.10 **A:** Pedigree of family with MINSHL (maternal inheritance). **B:** Pedigree of family with MINSHL (paternal inheritance).

imprinting. Beckwith-Wiedemann syndrome is a disorder of genetic imprinting coincidentally described by Hans-Rudolf Wiedemann in Germany and J. Bruce Beckwith of Loma Linda University, California in the 1960s. Beckwith-Wiedemann syndrome is the most common overgrowth syndrome. It is characterized by gigantism, macroglossia, anterior abdominal wall defects (most commonly congenital exomphalos), neonatal hypoglycemia,

organomegaly, and the development of multiple tumors during childhood, most commonly Wilms tumors (16–18). *H19*, also known as *BWS*, has been found to be associated with Beckwith-Wiedemann syndrome. The paternal allele of the *H19* gene is always silenced, and only the maternal allele is expressed. Interestingly, variability in *H19* or *BWS* has been associated with tumorigenicity and variable degree of aggressive behavior of certain tumors (19–21). Similarly, the cyclin-dependent kinase inhibitor 1C gene, also known as *CDKN1C* or *p57KIP2*, has been implicated in Beckwith-Wiedemann syndrome (22). *CDKN1C*, like *H19* undergoes the process of imprinting and only the maternal allele is expressed. *CDKN1C* is proposed to be a tumor suppressor gene that, when mutated, leads to the formation of various tumors (22,23). *Insulin-like growth factor 2 gene* (*IF2*) has also been implicated in the presentation of Beckwith-Wiedemann syndrome (24). In the case of *IF2*, in the normal situation, only the paternal copy of the allele is expressed. In tumors derived from patients with Beckwith-Wiedemann syndrome, a lack of imprinting has been demonstrated with both alleles being expressed in association with the disease.

Additional syndromes associated with genetic imprinting include Angelman syndrome, Prader-Willi syndrome, and Silver-Russell syndrome. Angelman syndrome is characterized by developmental delay, sleep disturbance, seizures, movement and balance disorders, microcephaly, and an unusually happy demeanor. Aberrations in *UBE3A* expression that codes for ubiquitin ligase have been implicated in Angelman syndrome. Angelman syndrome is caused by paternal imprinting of a normal *UBE3A* gene located on chromosome 15q11–13 with associated maternally inherited deletion or inactivation of the same genes (25). Converse to Angelman syndrome, Prader-Willi syndrome is caused by maternal imprinting of a normal *UBE3A* gene located on chromosome 15q11–13 with associated paternally inherited deletion or inactivation of the same genes (26). Prader-Willi syndrome is characterized by hypotonia, short stature, hyperphagia, obesity, behavioral issues, hypogonadism, and mental retardation. Silver-Russell syndrome is characterized by intrauterine growth restriction, dwarfism, hypoglycemia, failure to thrive, blue sclera, hemihypertrophy, craniofacial dysostoses, clinodactyly, hypotonia, precocious puberty, and cardiac defects (27,28). Silver-Russell syndrome has been associated with anomalies in chromosome 7 and 11 (29). Hypomethylation of the imprinting control region 1 (ICR1) in 11p15.5 has been demonstrated to affect the expression of *IGF2* and *H19* in association with Silver-Russell syndrome (24,29,30).

Additional Epigenetic Influences

Inheritable changes in phenotype or gene expression caused by mechanisms other than changes in the underlying DNA sequence refers to epigenetics. Gene silencing is a major component of epigenetic phenomenon. Gene silencing is a regulatory process by which certain genes are inactivated by mechanisms other than genetic modifications. This process typically involves DNA methylation or histone acetylation. Genetic imprinting as described above is an example of gene silencing. Genetic imprinting as described above is one of the most common forms of epigenetics by which DNA methylation and histone acetylation lead to the silencing of a specific gene allele based upon it pattern of inheritance. Additional forms of genetic silencing include transposon silencing, transgene silencing, transcriptional gene silencing, and RNA-directed DNA methylation.

Bookmarking is an epigenetic mechanism by which cellular memory is passed to subsequent cellular generations. Patterns of gene expression in the cell are transmitted through cellular memory by bookmarking though mitosis (31–33). This process is critical in the maintenance of cellular phenotype in the cellular lineage. This is accomplished by noncompaction of gene promoters, which are marked for expression during mitosis. Bookmarking may occur via gene silencing by DNA methylation, transcriptional regulation by histone modifications, regulation of gene expression by noncoding small RNA molecules, and retention of regulatory machinery on target gene loci for activation and repression (31–33).

X chromosome inactivation describe the process by one of the two inherited copies of the X chromosome in females is inactivated. In X chromosome inactivation, one copy of the X chromosome is silenced by packaging into heterochromatin, which prevents active transcription. This inactivation occurs in a random fashion in which either the maternal or paternal copy of the X chromosome may be inactivated. Similar to gene silencing, X chromosome inactivation may be associated with high levels of DNA methylation and histone acetylation (34).

Additional forms of epigenetic influence include paramutation, reprogramming, and position effect. Paramutation refers to the interaction between two alleles of a single locus, which results in a heritable change of one allele that is induced by the other allele. Reprogramming describes the process by which epigenetic markers are erased and remodeled. Position effect describes the effect of change in chromosome location on the expression of a gene.

Digenic Inheritance

Digenic inheritance or diallelic inheritance refers to coinheritance of mutation at two distinct genes or genetic loci that produce the phenotype of disease. There are a number of otolaryngologic disorders and syndromes that have been implicated to have a digenic mode of inheritance. There is evidence that certain forms of Usher type 1 syndrome may be transmitted via a digenic pattern of inheritance. Familial studies have implicated mutations in the *CDH23*

and *PCDH15* genes, which code for cadherin 23 and protocadherin 15, respectively, in the etiology of Usher type 1 syndrome (35). Bardet-Biedl syndrome, characterized by obesity, retinal dystrophy, polydactyly, renal malformation, mental retardation, and hypogenitalism, has been demonstrated to have a diallelic mode of inheritance and, in some cases, triallelic inheritance (36). Certain forms of nonsyndromic hearing loss have been demonstrated to be associated with digenic inheritance of mutation in gap junction proteins genes *GJB2* and *GJB6* (37). Digenic inheritance has also been demonstrated in Waardenburg syndrome type II with ocular albinism (38,39). Additionally, certain forms of hypertrichosis have been associated with digenic mutation at the 12q21.2–q22 and 16q21–q23 loci (40).

Complex Genetics

Complex genetics or polygenic inheritance refers to the pattern of inheritance by which multiple genes in combination lead to the phenotype of disorders or disease. Additional factors including lifestyle and environment often influence the phenotype of disease presentation in polygenic inheritance. The vast majority of inherited traits are transmitted via polygenic inheritance. Because of the multifactorial etiology associated with polygenic disorders, it can sometimes be difficult to quantify the probability by which inheritance may be conferred. Common disorders such as hypertension and obesity are frequently encountered examples of disorders with polygenic inheritance. Within otolaryngology, the most commonly cited disorders with polygenic inheritance are cleft lip and cleft palate. The etiology of cleft lip and cleft palate is thought to be complex involving both major and minor genetic influences with variable interactions from environmental factors (41).

Chromosomal Anomalies

In addition to the patterns of genetic transmission described above, chromosomal anomalies are responsible for a number of disorders. Chromosomal anomalies may occur sporadically, or they may be transmitted from generation to generation. Sporadically occurring chromosomal anomalies are more likely to be genetically lethal that inherited anomalies. Chromosomal anomalies take many forms.

Aneuploidy is one of the most common classes of chromosomal anomalies. Aneuploidy refers to an abnormal number of chromosomes. This typically occurs sporadically. The most commonly encountered example of aneuploidy is of trisomy 21 or Down syndrome. In Down syndrome, individuals possess an extra copy of chromosome 21. Patients typically present with a constellation of symptoms and characteristics including impairment in cognitive ability, microgenia, macroglossia, epicanthic folds, upslanting palpebral fissures, short limbs, single transverse palmar crease, high arched palate, short stature, hypotonia, Eustachian tube dysfunction, otologic anomalies, and cardiac anomalies. Down syndrome has also been associated with increased risk of developing certain malignancies including leukemia, retinoblastoma, and germ-cell tumors (42). The presentation of trisomy is often incompatible with life. Forms of trisomy that are compatible with live births include trisomies 9, 13, 18, and 16. Trisomy 9 is characterized by micrognathia, low-set ears, upslanting palpebral fissures, high arched palate, webbed neck, microcephaly, cranial dysostosis, cleft palate, short sternum, rocker bottom feet, cardiac anomalies, mental retardation, and renal anomalies (43). Infants with trisomy 9 often succumb within the first few months of life secondary to feeding difficulties, respiratory deficits, and major organ system dysmorphisms. Trisomy 13, also known as Patau syndrome, is associated with craniosynostosis, upslanting palpebral fissures, broad nose, cleft lip, cleft palate, anteverted nares, micrognathia, small, dysplastic and low-set ears, severe mental retardation, intrauterine growth restriction, cardiac anomalies, and postaxial polydactyly (44,45). Intrauterine growth restriction, clenched hands, rocker bottom feet, low-set or malformed ears, facial clefts, esophageal atresia, renal anomalies, cardiac defects, scalp anomalies, and central nervous system deformities are characteristic of trisomy 18 (46,47). The lifespan for the majority of patients with trisomy 18 is less than 1 year (46,47).

Aneuploidy may also occur in association with the sex-linked chromosomes. This may occur in the form of trisomy X, XYY, XXY, and XXYY. Trisomy X has been associated with hypertelorism, broad nasal dorsum, and recurrent infection, but otherwise, these patients are generally physically and developmentally indistinct from siblings without trisomy presentation (48). Related to trisomy X is the aneuploidy 47 XYY. Similar to trisomy X, 47 XYY syndrome patients typically present with a normal phenotype and are often unaware of their chromosomal anomaly. Reports have, however, linked 47 XYY with infertility (49,50). Klinefelter syndrome (47, XXY) is the second most common aneuploidy and the most commonly encountered sex-linked chromosomal disorder in males (51,52). Klinefelter syndrome is associated with tall stature, palatal cleft, clinodactyly, hypergonadotropic hypogonadism, speech and motor delays, and learning disabilities (52). Rarely, additional sex-linked aneuploidy syndromes, including 48, XXYY, 48, XXXY, and 49, XXXXY, have been described (52).

Chromosomal anomalies may also take the form of chromosomal loss. Chromosomal losses are typically not well tolerated and most commonly precipitate death *in utero*. The most commonly encountered example of chromosomal loss is Turner syndrome (45, X) in which one copy of sex chromosome is lost. However, even in the case of Turner syndrome, the vast majority of fetuses succumb prior to term birth. Those who survive present with characteristic findings of short stature, webbed neck, broad chest,

low frontal hairline, low-set ears, gonadal dysfunction, amenorrhea, infertility, cardiac anomalies, renal anomalies, hypothyroidism, hearing loss, visual disturbance, diabetes, and cognitive deficits.

Chromosomal anomalies may also take the form of rearrangement. Chromosomal rearrangements may take the form of deletions, duplications, translocations, or inversions. Deletions and duplications are more likely to be associated with the phenotype of mental retardation, growth restriction, and multiple congenital malformations, all of which is dependent upon the affected gene. In most cases, a loss of greater than 0.5% or loss of greater than 1% of genetic material is required to produce the phenotypic effect. Translocations and inversions most commonly produce a normal phenotype.

Microdeletion is a common etiology of various syndromes. In microdeletions, duplication or deletion occurs within a small chromosomal segment containing a limited number of linked but functionally unrelated genes. Microdeletion syndromes typically occur sporadically; however, inheritance of microdeletions may occur if the microdeletion results in a balanced chromosomal rearrangement. There are various microdeletion syndromes that are encountered within otolaryngology practice.

Of particular interest is microdeletion within the short are of chromosome 22, the 22q11.2 deletion. Deletions within this region of chromosome 22 have been linked to numerous syndromes including DiGeorge syndrome, velocardiofacial syndrome, CHARGE, and Shprintzen syndrome as well as certain forms of craniocerebellocardiac syndrome, Bernard-Soulier syndrome, Opitz-Frias syndrome, and Cayler cardiofacial syndrome (53–58). The presence of various syndromes associated with a deletion within the chromosomal region is secondary to variability in breakpoints and degree of involvement of the microdeletion. Additional examples of microdeletion syndromes encountered in otolaryngology practice include Williams syndrome (deletion within the q11.23 region of chromosome 7) and Smith-Magenis syndrome (17p11.2 deletion) (59,60).

GENETIC DISORDERS IN OTOLARYNGOLOGY: HEAD AND NECK SURGERY

There are a number of genetic disorders that are encountered within otolaryngology practice. This section is designated to highlight the genetic disorders encountered within the various subspecialties of otolaryngology. The list of disorders presented below is by no means meant to be all inclusive.

Genetic Disorders in Otology and Neurotology

As discussed previous within of this chapter, there are various otologic disorders that are associated with genetic etiology. The most commonly encountered genetic disorders in otology are associated with the phenotype of hearing loss. Approximately half of all congenital sensorineural hearing loss is of hereditary etiology. Among the patients with hereditary sensorineural hearing loss, approximately 70% to 80% of cases are associated with nonsyndromic hearing loss. Autosomal recessive inheritance accounts for approximately 75% to 85% of all nonsyndromic hearing loss. Autosomal dominant inheritance accounts for approximately 15% to 20% of nonsyndromic hearing loss, and approximately 1% to 3% of nonsyndromic hearing loss represents an X-linked pattern of inheritance. Mutations within connexin 26 (*GJB2*) account for up to 50% of all congenital recessive nonsyndromic hearing loss (called DFN1). There are multiple mutations within this gene that have been identified in association with nonsyndromic hearing loss, and several are common; four of the most common are 35delG (deletion of guanine at the 35th position in the gene sequence), 167delT, 235delC, and W24X (substitution of tryptophan by another amino acid at the 24th position in the protein). 35delG and W24X are common in many populations, while 167delT and 235delC are common in individual of Ashkenazi Jewish and Asian descent, respectively.

There are various forms of inherited syndromic sensorineural hearing loss. There are over 400 syndromes with associated hearing loss. Autosomal recessive forms of syndromic hearing loss include Usher syndrome, Refsum disease, Jervall Lange-Nielsen syndrome, Goldenhar syndrome, and Pendred syndrome.

Usher syndrome is associated with the phenotype of congenital sensorineural hearing loss, progressive retinitis pigmentosa, vestibular dysfunction, mental retardation, cataracts, and decreased cardiac conduction. Usher syndrome may be transmitted by an autosomal dominant or X-linked pattern of inheritance, but the primary mode of inheritance is autosomal recessive. Mutations within the *CDH23*, *CLRN1*, *GPR98*, *MYO7A*, *USH1C*, *USH1G*, and *USH2A* gene have been identified as causes of Usher syndrome (61–64). There are three identified types of Usher syndrome: (a) Usher type I, which is characterized by profound congenital sensorineural hearing loss, no vestibular response, and legal blindness by early adulthood; (b) Usher type II, which is characterized by moderate to severe congenital sensorineural hearing loss, legal blindness by mid-adulthood, and normal vestibular function; and (c) Usher type III, which is characterized by progressive sensorineural hearing loss, varied progressive blindness, and progressive vestibular dysfunction. Digenetic or polygenetic inheritance has been proposed in the pathogenesis of Usher type III.

Refsum disease is an autosomal recessive neurocutaneous syndrome characterized by peripheral polyneuropathy, cerebellar ataxia, retinitis pigmentosa, sensorineural hearing loss, and ichthyosis. Two genes have been identified in association with Refsum disease. Ninety percent

of all cases of Refsum disease are caused by mutations within the *PHYH* gene with the remainder of cases being linked to mutations within the *PEX7* gene (65–67). Both genetic mutations lead to deficient activity of the peroxisomal enzyme, phytanoyl-CoA hydroxylase, a peroxisomal enzyme leading to disruption in phytanic acid breakdown.

Jervell Lange-Nielsen syndrome is an autosomal recessive disorder associated with the phenotype of sensorineural hearing loss with associated cardiac dysfunction, namely, prolonged Q-T interval. In association with the presentation of a prolonged QT interval, patients with Jervell Lange-Nielsen syndrome have the propensity for cardiac arrhythmia, cardiac syncope, and sudden death. Mutations within two genes have been associated with the phenotypical presentation of Jervell Lange-Nielsen syndrome, *KCNE1* and *KCNQ1* (68,69). Both genes code for proteins that are critical in potassium channel function.

Goldenhar syndrome is characterized by various otologic findings associated with the phenotype of conductive hearing loss. These include preauricular appendages, pinna abnormalities, aural atresia, ossicular malformation, abnormal development of the facial nerve, anomalies of the stapedius muscle, abnormalities of the semicircular canals and anomalous oval window. Additionally, patients with Goldenhar syndrome may present with the phenotype of hemifacial microsomia, epibulbar dermoids, colobomas of the upper eyelid, vertebral abnormalities, and mild mental retardation. The mode of transmission for Goldenhar syndrome is of an autosomal recessive mode of transmission. The genetic basis for Goldenhar syndrome, however, has not yet been identified.

Alterations within the pendrin protein have been identified as the etiologic factor in the development of Pendred syndrome. The pendrin protein is a transporter protein; dysfunction of the pendrin protein leads to dysfunction of chloride, iodide, and bicarbonate ion transport. The pendrin protein is encoded by the *SLC26A4* gene; this gene has been found to be mutated in patients with Pendred syndrome (70). Pendred syndrome is inherited via an autosomal recessive pattern of inheritance and is associated with the phenotype of enlarge vestibular aqueduct, severe to profound sensorineural hearing loss, Mondini malformation, and euthyroid goiter.

There are a number of autosomal dominant syndromes associated with the phenotype of hearing loss. A sample list of these disorders include Stickler syndrome, BOR syndrome, Treacher-Collins syndrome, Waardenburg syndrome, Apert syndrome, Crouzon syndrome, Bjornstad syndrome, Keipert syndrome, NF1, and neurofibromatosis type 2 (NF2). This list represents the most frequently encountered autosomal dominant disorders of hearing loss in otolaryngology.

Stickler syndrome presents with the phenotype of progressive sensorineural hearing loss, marfanoid habitus, ocular abnormalities (retinal detachment, cataracts, and myopia), arthritic abnormalities (precocious arthritis and joint hypermobility), and Pierre Robin sequence. Mutations within genes responsible collagen production, processing and assembly have been associated with Stickler syndrome. These genes include *COL2A1*, *COL9A1*, *COL11A1*, and *COL11A2* (71,72). *COL2A1* is most commonly associated with Stickler type 1. Mutations within the *COL9A1* gene are more commonly associated with an autosomal recessive pattern of inheritance.

BOR syndrome, also known as Melnick-Fraser syndrome, is characterized by the phenotype of renal anomalies ranging from mild anomalies to agenesis, pinna deformities, preauricular pits, preauricular fistulas, preauricular tags, mixed hearing loss, and Mondini malformation. Mutation within the *EYA1* gene is most commonly associated with BOR syndrome. However, mutations within the *SIX1 and SIX5* genes have also been associated with BOR syndrome demonstrating genetic heterogeneity (more than one gene causing the same phenotype).

Treacher-Collins syndrome is associated with the phenotype of sensorineural, conductive or mixed hearing loss secondary to auricular deformities, aural atresia, external auditory canal stenosis, preauricular fistulas, ossicular malformation, and enlarged vestibular aqueduct. Treacher-Collins syndrome patients have normal intelligence and may present with aberrant facial nerve, Mondini malformation, zygomatic hypoplasia, mandibular hypoplasia, downward slanting palpebral fissures, coloboma of the lower eyelid, and palatal defects. Mutations within the *TCOF1* gene encoding for the treacle protein, critical to prenatal bone and soft tissue development, have been identified in association with Treacher-Collins syndromes (73–75).

Waardenburg syndrome is an autosomal dominant disorder characterized by pigmentary anomalies (i.e., heterochromia iridis, skin depigmentation, white forelock) craniofacial anomalies (i.e., dystopia canthorum, synophrys, and broad nasal dorsum), and sensorineural hearing loss. The genetic mutation most commonly cited in association Waardenburg syndrome is *PAX3*, which is responsible for type I and III Waardenburg syndrome (76–78). Additionally *MITF* and *SNAI2* mutations have been associated with Waardenburg type II; mutations within the *SOX10*, *EDN3*, and *EDNRB* genes have been associated with Waardenburg type IV, which presents with an autosomal recessive mode of inheritance (76–78).

Additional syndromes with otologic manifestations presenting with an autosomal dominant mode of inheritance include Apert syndrome, Crouzon syndrome, NF1, and NF2. Apert syndrome is caused by mutation within the *FGFR2* gene; similarly, Crouzon syndrome is caused by mutations within the *FGFR* gene. NF1 is associated with mutations in the neurofibromin gene on chromosome 17. Mutations within the merlin gene on chromosome 22 are associated with NF2.

A number of X-linked syndromes have been identified with otologic manifestations as well. Keipert syndrome,

or nasodigitoacoustic syndrome, which is characterized by misshaped nose, broad thumbs and halluces, brachydactyly, sensorineural hearing loss, and facial dysmorphisms, has been found to be caused by mutations within the q22.2–q28 positions on the X chromosome (79–81). Alport syndrome, characterized by ocular, renal and otologic anomalies, is associated with mutations within the type IV collagen genes on the X chromosome. Norrie syndrome (SNHL and blindness) is associated with mutations in the NDP gene on chromosome X. Otopalatodigital syndrome is caused by mutations within the *FLNA* gene on the X chromosome. Wildervanck syndrome (abducens palsy, cervical fusion, and SNHL or mixed hearing loss) is attributed to an X-linked dominant mode of inheritance.

Mitochondrial genomic deletions have been associated with the phenotype of sensorineural hearing loss. Acquired mitochondrial genomic deletions have been associated with the phenotype of age-related hearing loss (82). Certain forms of nonsyndromic and aminoglycoside-induced hearing loss have been found to be inherited through mitochondrial genomic deletions (83,84).

Genetic Disorders in Head and Neck Cancer

Genetics plays a critical role in head and neck cancer. Mutations within proto-oncogenes and tumor suppressor genes have been found to be key etiologic factors in various forms of sporadic head and neck cancer. Additionally, various genetic syndromes and disorders have been associated with inherited forms of head and neck cancer.

A number of proto-oncogenes and tumor suppressor genes have been identified in conjunction with squamous cell carcinoma of the head and neck. *p53* is a commonly encountered tumor suppressor gene located at 17p13.1, which is involved in cell cycle regulation and apoptosis. Mutations within *p53* have been identified in on average 40% to 70% of head and neck squamous cell carcinoma (85–89). *Cyclin D1* is an oncogene whose products accelerate cell cycle progression. Normal gene products of *p16* and *p21* are essential in the suppression of cyclin and cyclin-dependent kinase pathways. The *bcl-2* is an oncogene that functions to inhibit apoptosis and counteract p53. The *RET* gene is a proto-oncogene that is a cell surface tyrosine kinase receptor that is involved in the signal transduction pathway for cell growth. Alterations in the expression of each have been implicated in the phenotypical presentation of head and neck squamous cell carcinoma (90–93).

Additionally, genetic inheritance has been found to play a critical role in the development of various head and neck cancers including esophageal cancer, thyroid cancer, and cutaneous malignancies. Both Plummer-Vinson syndrome and tylosis are disorders associated with an increased incidence of esophageal cancer. Plummer-Vinson syndrome is a disorder of complex genetics with both genetic predisposition and environmental factors lead to the phenotypical presentation of disease (94). It is characterized by dysphagia, esophageal strictures, glossitis, iron deficiency anemia, cheilosis, koilonychias, splenomegaly, and squamous cell carcinoma of the postcricoid region or cervical esophagus. Tylosis is an autosomal dominantly inherited disorder characterized by esophageal cancer and hyperkeratosis of the palms and soles. Mutations within the *TOC* gene located on chromosome 17q25 have been implicated in the phenotype of tylosis (95).

Thyroid cancer has been found to be associated with a variety of syndromes including Cowden syndrome, Gardner syndrome, Werner syndrome, and the multiple endocrine neoplasia (MEN) type II syndromes. Cowden syndrome is an autosomal dominant disorder characterized by multiple trichilemmomas; gingival fibromatosis; hamartomas of the breast, thyroid, and gastrointestinal tract; and an increased risk for breast cancer, thyroid adenomas, and thyroid cancer. Mutations within the tumor suppressor gene *PTEN* have been implicated in the inheritance of Cowden syndrome (96). Gardner syndrome is an autosomal dominantly inherited disorder with the phenotypical presentation of multiple epidermal cysts, thyroid carcinoma, facial bone osteomas, cutaneous fibromas, lipomas, leiomyomas of the gastrointestinal tract, and adenomatous polyps of the colon. Mutations within the *APC* gene located at the q21 loci of chromosome 5 are causative in Gardner syndrome (97). Mutations within the *WRN* gene, which encodes the Werner protein, are associated with Werner syndrome (98). The Werner protein is believed to function in DNA maintenance and repair. Werner syndrome is inherited by an autosomal recessive pattern of inheritance and is characterized by the phenotype of accelerated aging, short stature, and increased incidence of thyroid cancer and other malignancies. MEN type II is characterized by the phenotype of medullary thyroid carcinoma and is subdivided into two subgroups: MEN IIA (medullary thyroid carcinoma, pheochromocytoma, parathyroid adenoma/hyperplasia, and hyperparathyroidism) and MEN IIB (medullary thyroid carcinoma, pheochromocytoma, marfanoid habitus, multiple mucosal neuromas, hyperplastic corneal nerves). Mutations within the *RET* gene are associated with the MEN II syndromes (99).

Various cutaneous malignancies manifesting within the head and neck are associated with a genetic mode of transmission, namely, Gorlin syndrome and xeroderma pigmentosa. Gorlin syndrome, also known as nevoid basal cell carcinoma syndrome, is an autosomal dominant disorder caused by mutations within the tumor suppressor gene *PTCH1* (100). Gorlin syndrome presents with the phenotype of multiple basal cell carcinomas, odontogenic keratocyst, bifid ribs, scoliosis, fontal bossing, and mental retardation. Xeroderma pigmentosa is an autosomal recessive disorder characterized by sun sensitivity, ocular disorders and a greatly increased risk of cutaneous neoplasms including basal cell carcinoma, squamous cell carcinoma, and melanoma. Diallelic mutation in the *XPA*, *ERCC3*, *XPC*, *ERCC2*, *DDB2*, *ERCC4*, and *ERCC5* genes as well as

monoallelic mutation within the *ERCC1* and *POLH* gene have been associated with xeroderma pigmentosa (101).

Genetic Disorders in Rhinology

Osler-Weber-Rendu syndrome, also known as hereditary hemorrhagic telangiectasia, is an autosomal dominant disorder caused by defects within the contractile elements in vessels cause in most instances by mutations within the *ENG* or *ALK-1* gene (102). This results in telangiectasias and arteriovenous malformations within various organ systems, including the nose, lung, liver, gastrointestinal tract, and brain. One of the earliest manifestations of Osler-Weber-Rendu syndrome is recurrent, recalcitrant epistaxis and cutaneous telangiectasias.

Cystic fibrosis is an autosomal recessive disorder commonly encountered in the otolaryngology practice. Cystic fibrosis is caused by a mutation within the CF transmembrane conductance regulator (*CFTR*) gene housed within chromosome 7, which encodes a chloride channel protein. Mutations within this gene results in dysfunction in exocrine gland function including decreased chloride secretion and increased sodium and water reabsorption. The phenotypical presentation of cystic fibrosis includes chronic sinusitis, respiratory dysfunction, pancreatic insufficiency, and infertility.

Kartagener syndrome or primary ciliary dyskinesia is an autosomal recessive disorder characterized by ciliary dyskinesia resulting from deficiency in the ciliary outer dynein arm. The phenotype of Kartagener syndrome typically includes abnormal ciliary motion, impaired mucociliary clearance, otitis media, sinusitis, situs inversus, bronchiectasis, chronic cough, and male infertility. Because Kartagener syndrome is a genetically heterogeneous disorder, it has been a challenge to identify all of the genetic mutations in association with this disease process. To date, eight genes have been identified in association with Kartagener syndrome: *DNAI1*, *DNAH5*, *DNAH11*, *DNAI2*, *KTU*, *RSH9*, *RSPH4A*, and TXNDC3 (103).

Genetic etiologies for various inherited immunodeficiency syndromes have been elucidated. Common variable immunodeficiency is the most common form of hypogammaglobulinemia characterized by failure of B-cell maturation. The majority of cases are acquired in nature; however, 15% of patients possess the inherited form of disease. Numerous mutations have been identified in association with common variable immunodeficiency: an autosomal dominantly inherited mutation in the tumor necrosis factor receptor superfamily member 13B gene (*TNFRSF13B*) located at 17p11.2, an autosomal recessively inherited mutation in the inducible T-cell costimulator gene (*ICOS*) located at 2q33, and an autosomal recessively inherited mutation in the B-lymphocyte antigen CD 19 gene (*CD19*) located at 16p11.2. X-linked agammaglobulinemia is associated with mutation in the Bruton tyrosine kinase gene (*BTK*), which results in marked reduction in all classes of serum immunoglobulin and absent B cells. X-linked lymphoproliferative disorder, which is characterized by inappropriate immune response to EBV infection, severe or fatal infectious mononucleosis, dysgammaglobulinemia, and lymphoproliferative disorders typically B cell in origin, has been linked to mutations in the *SH2D1A* gene, which encodes the SH2D1A protein. Finally, autosomal recessive agammaglobulinemia results from mutations in mu immunoglobulin heavy chain gene (*IGHM*), gamma 5 light chain gene (*IGLL1*), B-cell linker protein gene (*BLNK*), and Ig alpha (*CD79A*).

Genetic Disorders in Laryngology

Within the otolaryngology practice, there are, additionally, various syndromes and disorders of genetic etiology that manifest with the phenotype of laryngeal disorder and dysfunction. Opitz-Frias syndrome is a congenital disorder inherited by an X-linked or autosomal dominant mode of inheritance. It is characterized by hypertelorism, cleft lip, cleft palate hypospadias, and laryngeal cleft. The X-linked form of Opitz-Frias syndrome is associated with a mutation within the *MID1* gene; the autosomal dominant form is associated with a mutation with in the short arm of chromosome 22, 22q11.2 (104,105). As mentioned previously, mutations within this same loci of chromosome 22 are associated with numerous syndromes including DiGeorge syndrome, velocardiofacial syndrome, conotruncal anomaly face syndrome, and Cayler cardiofacial syndrome.

Pallister-Hall syndrome is a rare autosomal dominant disorder with associated laryngeal anomalies. The phenotypes of laryngeal cleft, hypothalamic hamartoblastoma, hypopituitarism, imperforate anus, postaxial polydactyly, and bifid epiglottis are associated with Pallister-Hall syndrome. Mutations within the *GLI3* gene are causative (106).

Additionally, laryngeal clefting and tracheoesophageal fistulae are associated with VACTERL association (vertebral anomalies, anal atresia, cardiovascular anomalies, tracheoesophageal fistula, esophageal atresia, renal/radial anomalies, and limb defects). Various genetic disorders including Goldenhar syndrome, trisomy 18, and Klippel-Feil syndrome are associated with VACTERL.

Finally, among the laryngeal disorders of potential genetic inheritance is congenital (hereditary) angioedema. Approximately 75% of patients with congenital angioedema inherit the disorder via an autosomal dominant mode of inheritance; the remainder of cases present sporadically. Mutations within the *C1NH* gene resulting in a deficiency in the C1 esterase inhibitor are responsible (107–109).

DIAGNOSIS OF GENETIC DISORDERS

The diagnosis and treatment of the otolaryngologic patient with genetic disorders often requires a multidisciplinary approach with our genetic colleagues playing a critical and

integral role. Knowledge of the human genome and identification of the genetic etiology of a plethora of genetic disorders has facilitated the detection and diagnosis of various genetic disorders. As technology continues to advance, techniques for the diagnosis genetic disorders continue to evolve in terms of speed and accuracy.

Methods for genetic analysis and diagnosis may broadly be classified as indirect detection (linkage analysis) and direct detection methods. By and large, the vast majority of techniques utilized for diagnosis of genetic disorders are within the direct detection class of technology. Direct detection, however, requires knowledge of the gene and encountered mutations responsible for the disease phenotype is required. Several methods for direct analysis are available, which provide rapid and cost-effective detection of known mutations (Table 9.3). The most precise method of direct detection currently utilized is polymerase chain reaction analysis, which amplifies short sequences of single-stranded DNA homologous to genomic DNA allowing for evaluation of mutation within specific gene regions. Despite all of the technologic advances, the diagnosis of certain genetic disorders still poses a challenge particularly in disease processes with unidentified mutations or complex genetic etiologies.

MOLECULAR THERAPY IN GENETICS

The decoding of the human genome presents a world of opportunity for future innovation by means of molecular therapy. Although still in its infancy, molecular therapy houses great potential in advancing treatment in various disease processes that remain a therapeutic challenge. Stem cell therapy and genetic therapy stands on the horizon as potential therapeutic techniques that could revolutionize medical care.

TABLE 9.3 METHODS USED FOR DIRECT DETECTION OF GENETIC MUTATIONS

Direct Detection Techniques
Allele refractory mutation system
Allele-specific oligonucleotide hybridization
Deletion analysis
Denaturing gradient gel electrophoresis
Heteroduplex analysis
Mismatch cleavage (chemical or enzymatic)
Oligonucleotide ligation assay
Protein truncation test
Restriction enzyme analysis
Reverse dot blotting (DNA chip technology)
Sequencing
Single-strand conformation polymorphism analysis
Sizing of trinucleotide repeats
Southern blotting

Stem cells are pluripotent, progenitor cells with the propensity for differentiation into various cell and tissue types. Current research is underway to identify pathways to facilitate targeted differentiation of stem cells into specific cell and tissue types. The ultimate goal is one of replacement of absent or dysfunctional cell populations leading the presentation of various disease processes. There are currently five forms of stem cells under investigation: human embryonic stem cells, adult somatic stem cells (i.e., bone marrow stem cells), cord blood stem cells, fetal stem cells, amniotic stem cells, and recently developed induced pluripotent stem cells. For more than 30 years, bone marrow stem cell and, more recently, umbilical and core blood stem cells have been have been utilized successfully in the treatment genetically inherited hematogenous diseases including thalassemia major and sickle cell anemia (110–112). Stem cell therapy is currently under investigation in a wide range of disease processes including cardiovascular disease, diabetes mellitus, and cancer. The challenge remains in improving the accuracy and consistency of differentiation to ensure targeted issue differentiation as well as localization of stem cells to target tissue.

Genetic therapy is an experimental technique with the potential for correcting defective genes responsible for the disease phenotype. Gene therapy may be performed via several approaches including insertion of a normal gene into a nonspecific location within the genome to replace the nonfunctional gene, replacement of the abnormal gene with a normal gene through homologous recombination, repair of the abnormal gene through selective reverse mutation rendering the gene functional, and silencing or regulation of the abnormal gene through alteration of promoters. The most commonly employed mechanism of genetic therapy is the insertion of a normal gene in to the genome in a nonspecific location to replace the nonfunctional gene.

Gene insertion and replacement is commonly performed utilizing a viral vector targeted at cells expressing the disease phenotype. Infection of target tissue with the viral vector allows for unloading of the desired genetic material and incorporation of the desired normal gene into the target cell genome. Various viruses have been used as vectors in gene therapy including retroviruses, adenoviruses, adeno-associated viruses, and herpes simplex viruses. In addition to viral vectors, various other techniques have been described that are utilized less frequently. Liposomes, lipid spheres with aqueous cores, may be utilized to introduce therapeutic DNA material. Alternatively, therapeutic DNA may be introduced directly into target cell; however, this technique is limited in that it requires large volumes of DNA and is limited to use in only certain tissue types. Although the efficacy is limited, therapeutic DNA may also be introduced by chemically linking the DNA to specific cell receptor ligands.

In addition to genetic therapies targeted at the replacement on nonfunctional genes or silencing of malfunctioning

genes, research in genetic therapy has also been targeted at selective termination of target cell populations. This has been of particular interest in the management of head and neck cancers. Cell populations expressing certain genetic mutations in the form of marker proteins or receptors may be targeted in an attempt to alleviate the malignant cell presentation.

Throughout its history, research into genetic therapy has experienced a number of setbacks including fatally in early clinical trials. Despite this, genetic therapy houses great promise in the management of challenging and debilitating genetic disorders. Further research is necessary to perfect these techniques and ensure patient safety in this potentially revolutionary method of treatment.

HIGHLIGHTS

- Genetics are the backbone of human existence.
- DNA provides the basic code from which all proteins and enzymes essential to life are formed.
- DNA is transcribed to RNA, which in turn is translated into a series of nucleotide triplets that form proteins.
- Mendelian genetics describes autosomal dominant, autosomal recess, and sex-linked inheritance.
- Non-Mendelian forms on inheritance include mitochondrial inheritance, genetic imprinting, gene silencing, bookmarking, x-chromosome inactivation, digenic inheritance, complex genetics, and chromosomal anomalies.
- Genetic disorders may present with variable penetrance (proportion of individuals carrying a gene variant that express the phenotypical changes) or variable expression (variation in the phenotype associated with a genetic mutation).
- A wide variety of genetic disorders are encountered in the various subspecialties of otolaryngology.
- Various methods are on the horizon in the management of genetic disorders to correct genetic mutations including genetic therapy and stem cell therapy.

ACKNOWLEDGMENT

We would like to thank Sabrina M. Heman-Ackah for her contributions to this chapter.

Microbiology, Infections, and Antibiotic Therapy

10

Thuy-Anh N. Melvin *Murugappan Ramanathan Jr.*

INTRODUCTION

Infections of the ears, nose, throat, and head and neck constitute a tremendous number of physician office visits and subsequently antibiotic treatment. Therefore, it is crucial that the otolaryngologist be familiar with common infections of the head and neck and management of these disease processes. In this chapter, we provide a brief overview of commonly prescribed antibiotics and discuss their utility in treating otolaryngologic infections based on current evidence. Due to emerging trends of antibiotic resistance and the introduction of new antibiotics, the reader is urged to supplement this material with The Sanford Guide to Antimicrobial Therapy, the online Johns Hopkins Antibiotic Guide, as well as current infectious diseases literature.

Commonly Utilized Antimicrobial Agents in Otolaryngology

Listed below are brief overviews of commonly prescribed antibiotics, which include their mechanism of action and common side effects. The antimicrobial coverage is discussed in more detail in the management section.

Penicillins

Penicillins target actively dividing cells affecting the third stage of cell wall synthesis in bacteria. This group of drugs is active against gram-positive cocci (*Streptococcus*, Group A and B) and bacilli (*Corynebacterium*), gram-negative cocci (*Neisseria*) and bacilli (*Streptobacillus*), some anaerobes (*Fusobacterium*, *Clostridium*, *Bacteroides*), and other bacteria such as *Treponema*, *Leptospira*, *Enterobacter*, and *Acinetobacter*. Adverse reactions include 1% to 5% risk of rash, which does not preclude future use of penicillin since recurrence of rash only occurs in 50% of patients. More serious allergic reactions can involve anaphylaxis, hives, angioedema, and bronchospasm, which require lifelong contraindication to penicillin use. However, allergy testing for major and minor determinants of penicillin is available and currently identifies 90–97% of those with allergy to penicillin. There have also been reported cases of nephropathy. Resistance has emerged through alterations in penicillin-binding proteins, inability to penetrate bacterial cell walls via porin channel blockage, beta-lactamase production, and enzymatic hydrolysis of penicillin (1). The spectrum of coverage for the various types of penicillins is depicted in Table 10.1.

Cephalosporins

Similarly, cephalosporins act by inhibiting the third stage of cell wall development. They also affect the binding of specific proteins on cell membranes, cause cell permeability changes, and inhibit protein synthesis and autolysin release. There are four generations of cephalosporins with the first having the most gram-positive efficacy and with the third and fourth generations being more active against gram-negative anaerobes (see Table 10.2). A newer fifth-generation cephalosporin class is emerging with activity toward *methicillin-resistant Staphylococcus aureus* (MRSA) (2,3). Side effects include hypersensitivity, neutropenia, thrombopenia, gastrointestinal disturbances, and renal impairment. Resistance has evolved through beta-lactamase and decreased cell wall permeability. Since penicillins and cephalosporins are structurally related, patients with a penicillin allergy are often not given cephalosporins for concern for cross-reactivity. Studies have examined the tolerability of cephalosporins in penicillin-allergic patients and found that there is a low risk of allergic reactions or anaphylaxis. Generally, first-generation cephalosporins such as cephalexin and cefazolin show higher rates of allergic reactions in patients with penicillin allergy. On the other hand, second- and third-generation cephalosporins such as cefuroxime, cefprozil, and cefdinir seem to have lower rate of allergic reactions in people with penicillin allergy. Overall, the clinician must err on the side

TABLE 10.1 PENICILLIN ANTIBIOTIC COVERAGE AND RESISTANCE

Penicillin Class	Antibacterial Spectrum	Resistance Pattern
Penicillin G or V	*S. pyogenes* (group A beta hemolytic), some *S. pneumoniae*	*S. pneumoniae*
Aminopenicillins (ampicillin, amoxicillin)	*H. influenza*, *S. pneumonia* (intermediate resistance), *S. pyogenes*, *E. coli*, *Proteus*, anaerobes	*S. aureus* resistance, emerging resistance to *H. influenza*, *M. catarrhalis*, *S. pneumoniae*
Antistaphylococcal penicillins (methicillin, oxacillin, dicloxacillin, nafcillin)	*S. aureus* (Not MRSA)	MRSA strains
Antipseudomonas penicillins (IV only) (mezlocillin, ticarcillin, piperacillin)	*P. aeruginosa*	*S. aureus* and anaerobe resistance
Augmented aminopenicillins (combined with beta lactamase inhibitor): amoxicillin/clavulanate (PO), ampicillin/sulbactam (IV)	*S. aureus* (not MRSA), *H. influenza*, *M. catarrhalis*, *S. pneumoniae*, *S. pyogenes*, *E. coli*, *Proteus*, and anaerobes	Emerging resistance to *S. pneumoniae*
Augmented antipseudomonas penicillins (combined with beta lactamase inhibitor): ticarcillin/clavulanate (IV), piperacillin/tazobactam (IV)	*P. aeruginosa*, *S. aureus* (not MRSA), anaerobes	Some strains of *P. aeruginosa*

MRSA, methicillin resistant *S. aureus*.

of caution when giving a penicillin-allergic patient cephalosporins and an oral challenge under medical supervision is recommended prior to use (4,5).

Macrolides

Macrolides, for example, erythromycin, exhibit bacteriocidal activity by binding to the 50S subunit of the 70S rRNA complex, thereby inhibiting protein synthesis. Effective against similar pathogens such as penicillins, they are also effective against atypical bacteria such as *Mycobacterium*, *Legionella*, and *Actinomyces* species. Adverse reactions are hypersensitivity, gastrointestinal upset, and cholestatic hepatitis. Resistance in macrolides has emerged through alterations of the 50S subunit and plasmids, which primarily affects *Haemophilus influenza*, *Staphylococcus aureus*, and *Streptococcus pneumoniae*.

Clindamycin

Clindamycin inhibits protein synthesis by binding to the 50S ribosomal subunit. It is useful against anaerobic gram-negative (e.g., *Prevotella*, *Fusobacterium*, and *Bacteroides*), gram-positive cocci (e.g., *S. aureus*, community-acquired MRSA and *S. pneumoniae*), and aerobic gram-negative (e.g., *Pseudomonas*, *Legionella*, *H. influenzae*, and *Moraxella*) bacteria. Untoward reactions include the development of pseudomembranous colitis, nausea/diarrhea, hypersensitivity, and leukopenia.

TABLE 10.2 CEPHALOSPORIN ANTIBIOTIC COVERAGE AND RESISTANCE

Cephalosporin Class	Spectrum of Activity	Resistance Patterns
First generation: cephalexin (PO), cefazolin (IV)	*S. aureus* (not MRSA), *S. pyogenes*, some *S. pneumoniae*, *E. coli*, *Proteus*	Emerging *S. pneumonia and S. aureus* resistance *H. influenza*, *Pseudomonas*, and *M. catarrhalis* resistance
Second generation: cefuroxime, cefdinir, loracarbef, cefprozil, etc.	*H. influenza*, *S. pneumonia* (PCN susceptible), *S. pyogenes*, *M. catarrhalis*, *N. gonorrhoeae*	Emerging *S. pneumoniae* resistance Resistant to *Pseudomonas* and anaerobes
Third generation: ceftibuten (PO) cefotaxime (IV), ceftriaxone (IV) (Excellent CSF penetration)	*S. Pneumoniae* (all strains except multidrug resistant), *H. influenza*, *M. catarrhalis*, *N. meningitides/gonorrhoeae*	Resistant to *Pseudomonas*, Emerging resistance to *S. pneumonia*
Fourth generation (antipseudomonal): cefepime, ceftazidime	*P. aeruginosa*, *S. aureus*, multidrug resistant *S. pneumonia*	Emerging resistance to *S. pneumoniae* (similar to third generation)
Fifth generation: ceftaroline, ceftobiprole	MRSA (Not FDA approved as of 2011), *P. aeruginosa*, multidrug resistant *S. pneumonia*	None known

MRSA, methicillin resistant *S. aureus*; PCN, penicillin; MDR, multidrug resistant; CSF, cerebrospinal fluid; FDA, Food and Drug Administration.

Similar to macrolides, resistance has developed through alteration in the protein component of the 50S subunit.

Fluoroquinolones

Fluoroquinolones are bactericidal agents that work by interfering with DNA replication via inhibiting DNA gyrase and topoisomerase II enzymes. They work well against a broad range of bacteria including *Pseudomonas*, *Streptococcus pyogenes*, and *S. pneumoniae*, *S. aureus*, *Moraxella catarrhalis*, and *H. influenzae*. However, resistance has evolved rapidly through mutations in DNA gyrase and topoisomerase enzymes as well as plasmid-mediated resistance.

Fluoroquinolone antibiotics are associated with risk of neurotoxicity and multiple musculoskeletal complications, most commonly, tendon rupture (6). Although once the most commonly prescribed antibiotic to adults, a black box warning was issued by the Federal Food and Drug Administration in 2008 citing increased risk of tendon rupture and tendonitis (7). More recently, another black box warning for levofloxacin was issued from its manufacturer in 2011 for an increased risk of tendon rupture specifically in adults over 60 when given in combination with oral corticosteroids as is commonly prescribed to chronic rhinosinusitis (CRS) patients. Given this well-known side effect, judicious use of this antibiotic is recommended, and when prescribed, patients should be appropriately informed of this possible side effect.

Trimethoprim–Sulfamethoxazole

Trimethoprim and sulfamethoxazole act together synergistically by inhibiting sequential steps in the folic acid synthesis pathway. It is effective against *Escherichia coli*, *S. aureus, community-acquired MRSA*, and *Listeria*. Side effects include mild to severe hypersensitivity (especially in sulfa allergic patients), Stevens-Johnson syndrome, myelosuppression, mydriasis, agranulocytosis, and severe liver damage. Mechanisms of resistance include binding alterations due to folic acid enzyme mutations.

Aminoglycosides

Aminoglycosides, for example, gentamicin, tobramycin, and streptomycin, inhibit protein synthesis by binding to the 30S ribosomal subunit. This class of drugs is useful against aerobic, gram-negative bacteria such as *Pseudomonas aeruginosa*, *Acinetobacter*, *Enterobacter*, and some *Mycobacteria*. Adverse reactions to consider include nephrotoxicity and ototoxicity, which is mediated by injury to the outer hair cells of the cochlea, specifically in patients that harbor a mutation in the 12S rRNA gene (8,9). Since this mutation is maternally transmitted, eliciting a detailed history can often prevent unnecessary administration of aminoglycosides to susceptible patients preventing deafness.

Vancomycin

Like penicillins, vancomycin targets and interferes with proper cell wall formation in gram-positive bacteria. Vancomycin resistance can emerge from alterations in the tail amino acids to which the drug binds. Nephrotoxicity and ototoxicity have been reported but are rare adverse reactions. Red man syndrome is an infusion reaction that occurs a few minutes after infusion characterized by erythematous rash. It is related to nonspecific mast cell degranulation and is not an IgE-mediated phenomenon. Occasionally, angioedema and hypotension can happen. To prevent red man syndrome, slow infusion is recommended over at least 60 minutes at a maximum rate of 10 mg/min for doses greater than 500 mg. Antihistamines can be used for premedication.

Topical Application of Antibiotics

In light of recent studies that suggest that chronic otolaryngological infections such as sinusitis and otitis media may be caused by bacterial biofilms (10–13), concurrent topical application of antibiotics in addition to systemic antibiotics may be beneficial in disrupting biofilms (14). Although numerous antibiotics are utilized topically, their efficacy compared to oral antibiotics remains unclear. The best documented topical antibiotics are bacitracin/neomycin/polymyxin-B and mupirocin.

Combinations of bacitracin and neomycin/polymyxin-B, in the form of skin ointments and ototopical preparations (along with hydrocortisone), are utilized for localized skin infections, prevention of skin infections, and otitis externa/media (in the setting of myringotomy tubes). The combination of these agents has efficacy against most gram-negative and gram-positive aerobic organisms and *P. aeruginosa* (primarily polymyxin-B). In addition, fluoroquinolone-based ototopicals are also effective against *P. aeruginosa*. The primary adverse reaction of bacitracin/neomycin/polymyxin-B is hypersensitivity. Mupirocin is another topical antibiotic primarily used in the sinonasal cavities to eradicate colonization and infection by MRSA and works by binding to bacterial isoleucine tRNA ligase thereby interfering with protein translation of bacterial ribosomal RNA.

Antifungals

Although numerous antifungal compounds exist, the primary classes of drugs are azole antifungals and polyene antifungals. Azole antifungals (e.g., voriconazole, fluconazole, and ketoconazole) inhibit the enzyme lanosterol 14 α-demethylase, which allows conversion of lanosterol to ergosterol. Therefore, azole antifungals inhibit fungal growth by depleting ergosterol in the fungal membrane thereby disrupting its structure. In general, voriconazole is active against systemic fungal infections with *Aspergillus* and *Candida* but lacks efficacy against *Mucor*. In addition, fluconazole is effective against *Candida* and *Cryptococcus* and has excellent CSF penetration. A major disadvantage of azole antifungals is that they have numerous drug–drug interactions with common agents such as statins, oral anticoagulants, and phenytoin.

Polyene antifungals, such as amphotericin B, bind to ergosterol in the fungal cell membrane causing a change

in the transition temperature of the cell membrane. Ultimately, this results in a disrupted cell membrane and cellular electrolyte imbalance leading to fungal death. Intravenous amphotericin B is also active against serious systemic fungal infections such as *Aspergillus* and *Mucor* but carries potentially serious adverse reactions such as nephrotoxicity, hepatotoxicity, hypotension, high fever, and shaking chills. A newer liposomal formulation of amphotericin B is highly effective against *Aspergillosis* and *Candidiasis* refractory to traditional amphotericin with fewer side effects. Liposomal amphotericin B is also the drug of choice for empiric therapy of presumed fungal infections in patients with febrile neutropenia.

Newer more potent antifungals with fewer side effects have emerged in recent years such as caspofungin. Caspofungin exerts antifungal action through inhibition of β-(1,3)-D-glucan in the fungal cell wall, and is highly effective against invasive *Aspergillosis* in patients who are refractory to other antifungal therapy.

Antiviral Agents

Antiviral agents are rarely used in otolaryngologic infections since viral infections are usually self-limiting. Common antiviral agents such as acyclovir, valacyclovir, and famciclovir are used to treat Herpes simplex and zoster in the setting of Ramsay-Hunt syndrome and Bells palsy. Acyclovir, valacyclovir, and famciclovir are prodrugs that are converted into a phosphorylated form ultimately exerting antiviral activity by inhibiting viral DNA polymerase.

Emerging Pathogens in Head-and-Neck Infections

While numerous pathogens have been implicated in infections of the head and neck, much attention has focused on anaerobic infections, MRSA, *P. aeruginosa*, and *Aspergillus* infections.

Anaerobes

Anaerobes are very common in the mucosal membranes of the head and neck as well as normal skin flora (15). Anaerobic infections comprise a large portion of endogenous infections. Challenges in the management of these infections include their slow growth, increasing resistance, and polymicrobial nature. There are five categories of antimicrobial agents active against anaerobes: carbapenems, metronidazole, chloramphenicol, tigecycline, and combinations of penicillin and a beta-lactamase inhibitor.

Pseudomonas Aeruginosa

Infections of the head and neck due to *P. aeruginosa* are common under certain circumstances. Paranasal sinus culture samples from patients with cystic fibrosis most commonly grow out *P. aeruginosa* followed by *S. aureus* and *Streptococcus viridans* (16). In addition, CRS patients with relapsing mucopurulent infections frequently harbor *Pseudomonas* (17,18). The antibiotic categories to consider when choosing an effective therapy against *Pseudomonas* include: fluoroquinolones or augmented fluoroquinolones (pipericillin/sulbactam), aztreonam, cefepime, colistin, gentamicin (or tobramycin). Cultures with sensitivities are crucial as there is increasing resistance with certain fluoroquinolones, such as ciprofloxacin and levofloxacin, as well as anti-*Pseudomonas* penicillins such as ticarcillin (19). The primary mechanism of resistance is through multidrug efflux pumps with chromosomally encoded antibiotic resistance genes (*mexAB-oprM*, *mexXY*, etc.) (20,21). Recent studies have also shown that phenotypic resistance patterns may be due to biofilm formation with poor antibiotic penetration (22).

Methicillin-Resistant Staphylococcus aureus

The evolution of methicillin resistance in *S. aureus* was recently linked in part to the acquisition of the mecA gene, which encodes for a penicillin binding protein with low affinity for beta-lactam antibiotics (23). The mecA gene has therefore emerged into a molecular target for identifying MRSA and recent studies have identified new divergent homologues of mecA in *S. aureus* that were previously thought to be methicillin sensitive (24).

Community-acquired methicillin-resistant *S. aureus* (CA-MRSA) infections are a growing problem (25). Treatment can frequently be managed as an outpatient; however, when infections are severe, inpatient management is necessary. Chemotherapy options vary and reported resistance rates can range significantly as seen in Table 10.3 (26). MRSA outbreaks in hospitals pose a great challenge. One study looking at widespread use of topical mupirocin showed no advantage, whereas, increasing hand hygiene audits and staff training did correlate with better control of MRSA outbreaks in the ICU setting (27).

Aspergillus

Aspergillus is histologically distinct from other fungi through its septate hyphae with 45-degree branching, in contrast to nonseptate hyphae branching at 90 degrees, which is frequently seen with *Rhizopus* and *Mucor*. *Aspergillus* is a chronic colonizing pathogen of the paranasal sinuses and ear. In the sinuses, *Aspergillus* infection can manifest through various diseases. Invasive fungal sinusitis in the immunocompromised host can be managed with early detection, surgery, and recovery of host immunocompetence. Allergic fungal rhinosinusitis can be effectively managed with surgery and oral corticosteroids. Lastly, mycetoma (i.e., fungal ball) can usually be cured with surgery. In the setting of chronic antibiotic use, *Aspergillus* otologic infections can arise. This disease process usually resolves with the use of topical antifungals (28).

Antimicrobial Management of Common Otolaryngological Infections

Upper Respiratory Infections

Although upper respiratory infections (URIs) are frequently viral in etiology, they are most commonly treated

TABLE 10.3 ANTIMICROBIAL AGENTS EFFECTIVE AGAINST CA-MRSA AND THEIR RESISTANCE RATES

Antimicrobial Agent	Dosing	Adverse Reaction	Mechanism	Resistance (%)
Oral				
Ciprofloxacin	500 mg QD	Seizures, prolonged QTc, photosensitivity, tendon rupture	Topoisomerase II inhibition	7–85
Doxycycline	100 mg q12h	Tooth discoloration, bone toxicity, photosensitivity	Protein synthesis: inhibits 30S ribosomal subunit	0–20
Clindamycin	300–450 mg q6–8h	GI upset, *C. difficile* colitis	Protein synthesis: inhibits 50S ribosomal subunit	3–66
Trimethoprim–sulfamethoxazole	160 mg q12h	Stevens-Johnson syndrome, hyperkalemia, hypersensitivities	Inhibits folic acid synthesis and growth	0–10
Linezolid	600 mg q12h	Myelosuppression, monoamine oxidase inhibition	Protein synthesis by 23S ribosomal subunit	0–4
Parental				
Daptomycin	4 mg/kg q24h	Myopathies	Bacterial membrane disruption by forming transmembrane channels	0
Vancomycin	10–15 mg/kg q12h	Red man syndrome, nephrotoxic	Inhibits cell wall synthesis	0
Tigecycline	100 mg, then 50 mg q12h	Nausea/vomiting	Protein synthesis: 30S ribosomal subunit	0–1.5
Linezolid	600 mg q12h	As above	As above	As above
Topical				
Mupirocin	0.05%	Local site reaction	Binds to tRNA ligase and prevents translation of bacterial ribosomal RNA	30% recolonization within 4 wk of therapy

with antibiotic therapy. In order to differentiate between bacterial and viral infections, it is advisable to wait 5 to 7 days prior to initiating antimicrobial therapy. Amoxicillin is often the first-line agent for the most common otolaryngologic infections: acute otitis media (AOM), acute rhinosinusitis (ARS), and pharyngotonsillitis. Failure of amoxicillin therapy is frequently secondary to the emergence of beta-lactamase producing bacteria. In such cases, augmented penicillins with a beta-lactamase inhibitor such as amoxicillin/clavulanate are preferred. Also, cephalosporins can overcome beta-lactamase resistance and preserve interfering bacteria that help cure URIs (29).

Otitis Media

AOM is a very common medical condition in children. In many cases, AOM is self-limiting and therefore observation alone is a suitable starting point for uncomplicated cases in children older than 2 years of age when adequate follow-up can be ensured (30,31). *S. pneumoniae* and nontypeable *H. influenzae* are the two main pathogens (32). Spontaneous recovery is more commonly seen with AOM caused by *H. influenzae* than by *S. pneumoniae*; however, *H. influenzae* AOM is associated with older patients and recurrent disease (33). According to the American Academy of Pediatrics (AAP) and American Academy of Family Practice 2004 practice guidelines for AOM, amoxicillin, 80 to 90 mg/kg/d, is the recommended first-line antibiotic therapy geared towards these microbes. If there is no improvement after 48 to 72 hours, switching to a cephalosporin or augmented penicillin is recommended. The overall efficacy in antibiotic therapy in treating AOM remains controversial. A recent study by Coker et al. (34) reported that antibiotics are only modestly more effective than no intervention and can additionally cause adverse effects in 4% to 10% of children. On the other hand, Hoberman et al. (35) demonstrate the efficacy of antibiotics in AOM in a double-blinded placebo-controlled trial. Among 291 children aged 6 to 23 months randomized to placebo or amoxicillin/clavulanate, treatment with amoxicillin/clavulanate for 10 days tended to reduce duration of symptoms and reduced overall symptom burden and the rate of persistent signs of acute infection on otoscopy.

Despite the advent of the 7-valent pneumococcal conjugate vaccine (PCV7), AOM still continues to be a major reason for antibiotic prescriptions (36); however, the makeup of pathogens has evolved and the number of office visits for AOM has decreased (37). Six to eight years after the advent of the vaccine, nasopharyngeal and middle ear fluid composition has changed to have almost no vaccine-type stereotypes of *Streptococcus*. Nontypeable *H. influenzae* and non-PCV7 strains of *Streptococcus* continue to be major causes of AOM (38). In the first 2 years of life, the vaccine

is associated with reduced number of AOM episodes, need for ventilating tubes, and emergency visits (39). Since the introduction of this vaccination, *M. catarrhalis* has become more common as a cause of AOM in children (40). AOM caused by *M. catarrhalis* is thought to be milder than AOM from *S. pneumoniae*, which may help explain the decreased number of office and emergency visits. Additionally, the incidence of *S. aureus* AOM may have risen in the setting of pneumococcal vaccination (41).

AOM and otitis media with effusion (OME) should be distinguished for the management differs between the two disease entities. The Subcommittee on OME, which was convened by the AAP, the American Academy of Family Physicians (AAFP), and the American Academy of Otolaryngology—Head and Neck Surgery (AAO—HNS) released evidence-based guidelines for the management of OME in 2004 which do not support the use of antimicrobials as an effective long-term treatment. In some cases, antibiotics are an option if parents are against surgical management but are not considered first-line management for OME (42).

Chronic suppurative otitis media (CSOM) is characterized by a persistently draining ear with a nonintact tympanic membrane and can often cause destructive irreversible changes in the bony structure of the ear. Most CSOM infections are polymicrobial with *P. aeruginosa* and *S. aureus* along with anaerobes including *Peptostreptococcus*, *Bacteriodes*, and *Fusobacterium* (43). In general combination, antimicrobial therapy using clindamycin (due to the high rate of penicillin resistance) and fluoroquinolones (for antipseudomonal coverage) is utilized sometimes in combination with ototopical drops. Due to the chronic nature of this polymicrobial disease, middle ear cultures are often crucial to identify organisms and their antibiotic susceptibilities. In general, antimicrobial therapy alone is insufficient and tympanoplasty is usually required at a later age with cholesteatoma removal if present.

Although rare in the United States, tuberculosis is one of the most common infections of developing countries and can affect the middle ear. Tuberculosis otitis media is characterized by painless copious otorrhea, which typically fails first-line antimicrobial treatment. Examination often reveals multiple tympanic membrane perforations and granulation tissue. It can lead to sequelae such as bone erosion and hearing loss. Preauricular lymphadenopathy can be associated with this disease process. Management requires combination antitubercular therapy (44). Additionally, surgical treatment to remove necrotic bone and inflamed soft tissue and to improve middle ear ventilation may be warranted.

Lastly, otitis media can lead to extracranial and intracranial complications if left untreated. Extracranial complications include tympanic membrane perforation, subperiostial abscess, mastoiditis that can spread to soft tissue planes (Fig. 10.1), facial paralysis, petrositis, and labyrinthitis (45). Untreated otitis media can break down the natural barriers of the bony skull base and result in intracranial complications such as meningitis, extradural abscess, intracerebral/subdural abscess, subdural empyema, and otitic encephalitis.

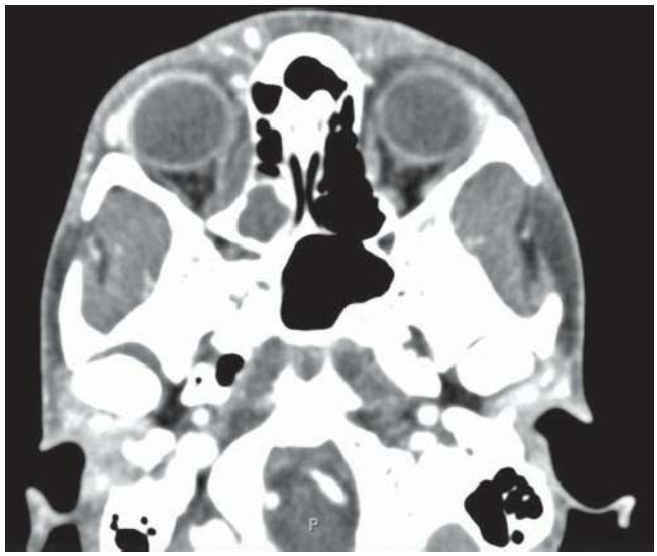

Figure 10.1 Maxillofacial CT scan in the axial plane without contrast. Right-sided subperiostial collection extending along the medial wall of the orbit with mild inflammatory changes in the adjacent medial extraconal space measuring 2 × 0.5 × 1.3 cm. This collection is causing mild mass effect on the medial rectus muscle. There also exists a small bony dehiscence of the right posterior lamina papyracea communicating with an opacified posterior ethmoid cell that is likely the origin of the subperiostial collection.

Otitis Externa

Otitis externa, also known as "swimmer's ear," is a cellulitic inflammation of the external auditory canal skin and soft tissue. Infection can alter the pH of the external auditory canal making bacterial growth more favorable. Reestablishing an acidic environment by using topical preparations, such as topical fluoroquinolones, can be achieved (46). The 2006 Clinical Practice Guideline recommends use of ototopical antibiotic drops as initial therapy in uncomplicated acute otitis externa limited to the external auditory canal skin (47,48). When a tympanic membrane perforation is present, care should be taken to not prescribe ototoxic drops. Systemic antibiotics are sometimes indicated if the infection has spread beyond the skin of the external auditory canal. Resistance to gentamicin and ciprofloxacin topical therapy for MRSA otorrhea is rapidly emerging; however, trimethoprim–sulfamethoxazole susceptibility remains largely intact (49).

Malignant necrotizing otitis externa (MNOE) is frequently a life-threatening condition that requires prolonged antibiotic management and therefore poses a diagnostic challenge. In one retrospective study, 68% of otolaryngologists were initially consulted for something other than MNOE in patients who ultimately had the diagnosis of MNOE (50). A significant risk factor is immunosuppression, for example, diabetes, chemotherapy, organ transplantation with immune modulating drug therapy, and HIV. There is a subset of necrotizing otitis externa that

is coined as benign necrotizing otitis externa (BNOE). It is characterized by soft tissue ulceration overlying bony necrosis found in the floor of the external auditory canal. Management of BNOE differs from that of MNOE in that although antimicrobial therapy is usually warranted, surgical debridement is usually not necessary (51).

Candida and *Aspergillus* are the most common fungal pathogens isolated in the setting of otomycosis (52). Patients with noninvasive otomycosis should be treated with debridement and topical antiseptics and acidifying agents such as acetic acid and isopropyl alcohol containing drops or Gentian violet. Occasionally, antifungal topical agents such as clotrimazole can be utilized.

Sinusitis

As with many URIs, most ARS is viral in etiology and a fraction of patients are thought to eventually develop a secondary bacterial infection. The most common bacteria implemented in community-acquired acute sinusitis with purulent drainage are *S. pneumoniae, H. influenzae, M. catarrhalis,* and *S. pyogenes* (53). However, in one retrospective study (54), the most common organism isolated from paranasal cultures in clinically infected patients was found to be *S. aureus*, 20% of which are MRSA. This may reflect the shift in causative bacteria in ARS—a phenomenon seen in AOM due to the advent of the pneumococcal vaccination.

Antibiotic use in acute bacterial rhinosinusitis (ABRS) has been controversial. There is some evidence of overprescribing of antibiotics in ABRS as clinical studies have confirmed that roughly 60% of presumed ABRS episodes have a bacterial etiology. In addition, recent data show that antibiotics are prescribed in 81% to 92% of ARS cases (55,56). Although there is no clear consensus regarding the management of presumed ABRS due to numerous conflicting studies in the literature, amoxicillin is the first-line therapy in children and adults with uncomplicated bacterial ABRS with symptoms persisting beyond 5 days (57–60). Other agents recommended for symptomatic relief include short-term topical decongestants, intranasal corticosteroids, and nasal saline. However, if symptoms do not improve after initiation of amoxicillin, changing to amoxicillin/clavulanate or a cephalosporin is recommended (29,61). A double-blinded randomized-controlled trial examining amoxicillin/clavulanate efficacy in the setting of pediatric ABRS found a significantly higher cure rate as reported by parents (62).

Although there is some overlap between ABRS and CRS, CRS tends to be more heterogeneous despite its classification by duration of illness greater than 12 weeks or with the presence of nasal polyps. The microbiology of CRS is distinct from ABRS. Most common isolates are *S. aureus* and anaerobic pathogens such as *Prevotella, Porphyromonas, Fusobacterium,* and *Peptostreptococcus* (63). Pediatric CRS may also involve colonization of the sinonasal tract and adenoid pad with coagulase-negative *Staphylococci* (40.8%), *S. aureus* (22.3%), *S. pneumoniae* (18.4%), *H. influenzae* (16.5%), and group A *Streptococci* (15.5%) (64). The pathogenesis of the inflammatory response in CRS is poorly understood and may arise independently from infection itself causing a defective mucociliary clearance ultimately setting the stage for further infections.

In terms of management, there is a lack of consensus for the treatment of CRS due to the paucity of controlled studies. The design and interpretation of CRS clinical trials have been hindered by the inherent heterogeneity of the disease. Although controversial, primary treatment generally involves empiric antibiotic therapy with coverage for both aerobic and anaerobic bacteria in addition to intranasal and oral corticosteroids. In addition, studies have demonstrated that antibiotic therapy for CRS is sometimes not effective (65) perhaps in part due to the complexity of the disease process (57,66) indicating a role for endoscopic sinus surgery. A recent multi-institutional prospective study by Bhandarkar et al. (67) demonstrates that endoscopic sinus surgery reduces overall antibiotic utilization in CRS and recurrent ABRS (67).

Topical antibiotic agents have been shown to have added benefit over placebo in CRS, specifically the use of mupirocin irrigations in patients with prior sinus surgery with active MRSA infections (14,68,69). Although topical preparations offer favorable localized delivery of medication thereby minimizing side effects, the mode of delivery (low pressure, high volume irrigation vs. nebulization) and the efficacy of various compounds including antifungal therapy remain inconclusive.

There are differences found between the bacteriology in patients undergoing primary versus revision endoscopic sinus surgery. Of those undergoing endoscopic sinus surgery, *P. aeruginosa* is significantly more common in those undergoing revision sinus surgery whereas *S. viridans* is significantly more common in those undergoing primary sinus surgery (70).

Nosocomial or "ICU" sinusitis often involves *P. aeruginosa* and MRSA. Empiric therapy usually entails IV cephalosporins or fluoroquinolones until endoscopically guided cultures can be obtained. Febrile neutropenic patients with sinusitis frequently harbor invasive fungal infection with *Aspergillus* or *Mucor*. Timely endoscopic evaluation with biopsy of mucosa is crucial. Although surgical debridement was once the primary modality of treatment adjuvant use of the newer more potent systemic antifungals such as voriconazole or amphotericin B is recommended (71,72).

Complications of sinusitis include involvement of adjacent structures such as the orbit and the skull base. Orbital complications secondary to acute sinusitis in children may become a precursor to meningitis and usually involve *S. pneumoniae* or *H. influenza*. Diagnosis should occur in a timely manner and treatment expedited with intravenous antibiotics that can penetrate the blood–brain barrier (ceftriaxone, or fluoroquinolones) in addition to clindamycin with or without surgical debridement depending on the presence of drainable subperiosteal or intraorbital purulence (73) (Fig. 10.2). Additional antibiotics can be added depending on the resistance patterns of *S. pneumoniae*.

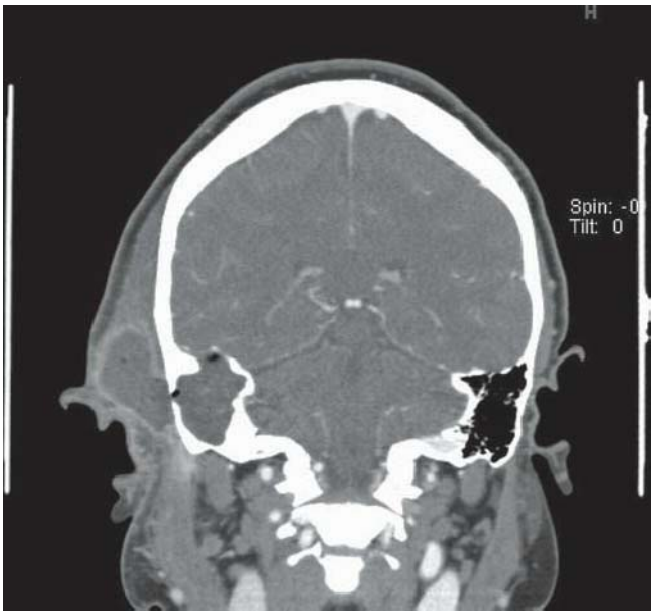

Figure 10.2 Temporal Bone CT in the coronal plane without contrast. The right mastoid cavity is opacified with soft tissue density and complete destruction of the septae. There is dehiscence of the medial wall, with mild inward bowing of the sigmoid sinus. There is dehiscence of anterior and anterolateral walls of the mastoid complex with a large well-formed abscess.

Pharyngitis

Pharyngitis is viewed as a self-limiting disease process in most scenarios. There are substantial discrepancies in the recommendations for the management of pharyngitis among national guidelines in Europe and North America. In select cases, where *Streptococcal* pharyngitis has been diagnosed with rapid antigen detection testing, patients should receive penicillin or amoxicillin or amoxicillin/clavulanate as first-line therapy for a total of 10 days (61,74) and cephalosporins can be used when the disease relapses (75). Macrolides or clindamycin can be reserved for penicillin-allergic patients.

Deep Space Neck Abscess/Peritonsillar Abscess

Acute tonsillitis can lead to a peritonsillar abscess (PTA) if not appropriately treated. PTAs and other deep neck abscesses are usually polymicrobial with anaerobic bacteria such as *Fusobacterium necrophorum* and group A *Streptococcus* involved (76). Treatment decisions are made empirically with clindamycin or augmented penicillins or on the basis of a gram stain of pus.

Supraglottitis

Acute supraglottitis, also known as epiglottitis, can be a challenging diagnosis to make for symptoms and signs can be nonspecific and can mimic a common URI (77).

In the era of post–*H. influenzae B* vaccination, epiglottitis is relatively rare and there has been a substantial shift in the patient demographics. After diagnosis is achieved, patients should be admitted for intravenous antibiotics with close monitoring of the airway. Effective antibiotic regimens have comprised of IV ceftriaxone and ampicillin/sulbactam (78). If securing the airway is necessary, intubation can be achieved with awake nasotracheal intubation and in some instances via direct laryngoscopy.

Croup

Croup has been defined as an acute clinical syndrome that typically affects those 6 years old or younger. The pathogenesis is thought to be from a viral URI that leads to upper airway inflammation characterized by edema of the subglottic mucosa. The effect on the upper airway can lead to untoward deterioration and urgent need for intubation. Corticosteroids are now an accepted part of the standard management of croup (79–81). In the setting of hypoxia, supplemental oxygen should be delivered.

Salivary Gland Infections

The parotid gland is the most common salivary gland affected by infectious inflammation. Risk factors for acute bacterial parotitis are dehydration and immunosuppression. Responsible pathogens include *S. aureus*, *Streptococcus* species, and anaerobes such as *Peptostreptococcus* and gram-negative bacilli (e.g., *Prevotella*, *Porphyromonas*, *Fusobacterium* species) (82,83). Empiric therapy can be commenced with clindamycin or augmented penicillins, but antibiotic therapy should be culture-directed whenever possible. If an abscess forms, surgical drainage is also necessary.

HIGHLIGHTS

- Macrolides and clindamycin work through inhibiting the 50S ribosomal subunit while aminoglycosides act on the 30S subunit.
- Amoxicillin is the first-line antimicrobial agents for the most common otolaryngologic infections including AOM and acute bacterial sinusitis.
- *S. pneumoniae* and *H. influenzae* remain the two most common bacteria in the pathogenesis of AOM; however, in the setting of vaccinations the specific types have evolved to include nontypeable *H. influenzae* and non-PCV7 strains of *Streptococcus*.
- MecA mediates methicillin resistance to *S. aureus* through encoding for an altered penicillin binding protein.
- *Pseudomonas* infections are commonly seen in chronic diseases such as CRS, acute diseases such as otitis externa, and nosocomial infections. Fluoroquinolones are effective agents; however, there is growing resistance as well as risk of tendon rupture that patients should be informed of prior to starting therapy. Resistance is mediated by efflux pumps and biofilm formation.

- Antibiotics should only be prescribed in presumed cases of ABRS after at least 5 days of observation. The role of antimicrobial therapy in CRS remains controversial due to the heterogeneity of the disease.
- Complications of both sinusitis and otitis media can result in orbital and intracranial extension, which can be managed with a combination of surgery and ceftriaxone and clindamycin or ampicillin/sulbactam.
- Pharyngitis is often a self-limited process; however, in the setting of positive rapid antigen testing, amoxicillin is first-line therapy.
- The most common infected salivary gland is the parotid gland and frequently *S. aureus* is the offending microbe.

Head and Neck Imaging

11

Tanya J. Rath

Due to advances in cross-sectional imaging, computed tomography (CT), magnetic resonance imaging (MRI), and ultrasound have largely replaced conventional radiography in head and neck imaging and are invaluable primary imaging modalities used to evaluate pathology in the head and neck. They are complementary to a thorough physical exam and essential to characterize the deep tissue extent of mucosal lesions as well as evaluate pathology originating in the other spaces of the neck. Nuclear medicine has poor spatial resolution but provides useful functional and metabolic information. This chapter provides an overview of the various imaging modalities available in the head and neck as well as describes the application, strengths, and weaknesses of these modalities as they pertain to head and neck imaging. A thorough discussion of the physics of these modalities and image interpretation is beyond the scope of this chapter and is described in detail in several dedicated imaging and physics textbooks (1–4).

COMPUTED TOMOGRAPHY

Imaging Principles

CT employs the use of ionizing radiation to image patients. An x-ray tube rotates 360 degrees around the patient, while a well-collimated x-ray beam is generated and passed through the patient. The beam is partly absorbed or scattered as it passes through the patient. Tissues of different density and thickness attenuate the beam to varying degrees. A circumferential bank of detectors opposite the beam measures the degree of x-ray transmission through the patient. Each volumetric imaging unit (voxel) is assigned a numeric value, called a Hounsfield unit (HU). Water is assigned a value of 0 HU. The matrix of HUs is then displayed in a gray scale, resulting in an anatomic cross-sectional image. Various algorithms can be applied to optimize evaluation of different structures such as bone, soft tissue, or lung parenchyma (Fig. 11.1).

Most scanners are now multidetector helical or spiral scanners in which the patient translates through the x-ray tube while it continuously rotates around the patient. Using this design, spatial resolution is improved and large volumes can be imaged with reduced scan time, resulting in greater anatomic coverage with decreased motion artifact. Data can be acquired in less than 1-mm-thick slices and reconstructed at various intervals in the axial, coronal, and sagittal planes. Images can be obtained during quiet respiration or in a short single breath hold and the entire neck can be scanned in less than 1 minute.

Applications and Technique by Region of Interest

Temporal Bone

CT is the study of choice to evaluate osseous integrity of the temporal bone including the otic capsule, ossicular chain, cortical plates, and air spaces. Main indications include evaluation of temporal bone fracture, congenital anomalies of the otic capsule, conductive hearing loss, inflammatory disease, and erosive neoplastic processes affecting the temporal bone.

Direct coronal images are typically no longer necessary due to high-resolution helical multidetector imaging. A small field of view is employed with a high-resolution matrix. Technique is optimized to evaluate bony detail and 0.5- to 0.625-mm-thick axial images and thin-cut coronal reconstructions are routinely provided (Fig. 11.2). Additional oblique reformats such as Stenvers view and Pöschl view can be useful to demonstrate semicircular canal dehiscence (Fig. 11.3). All data are displayed in bone algorithm windows. Thicker 2.5-mm axial images to evaluate the soft tissues and posterior fossa structures are useful as well. Contrast is typically not necessary but can be helpful in evaluating the soft tissues

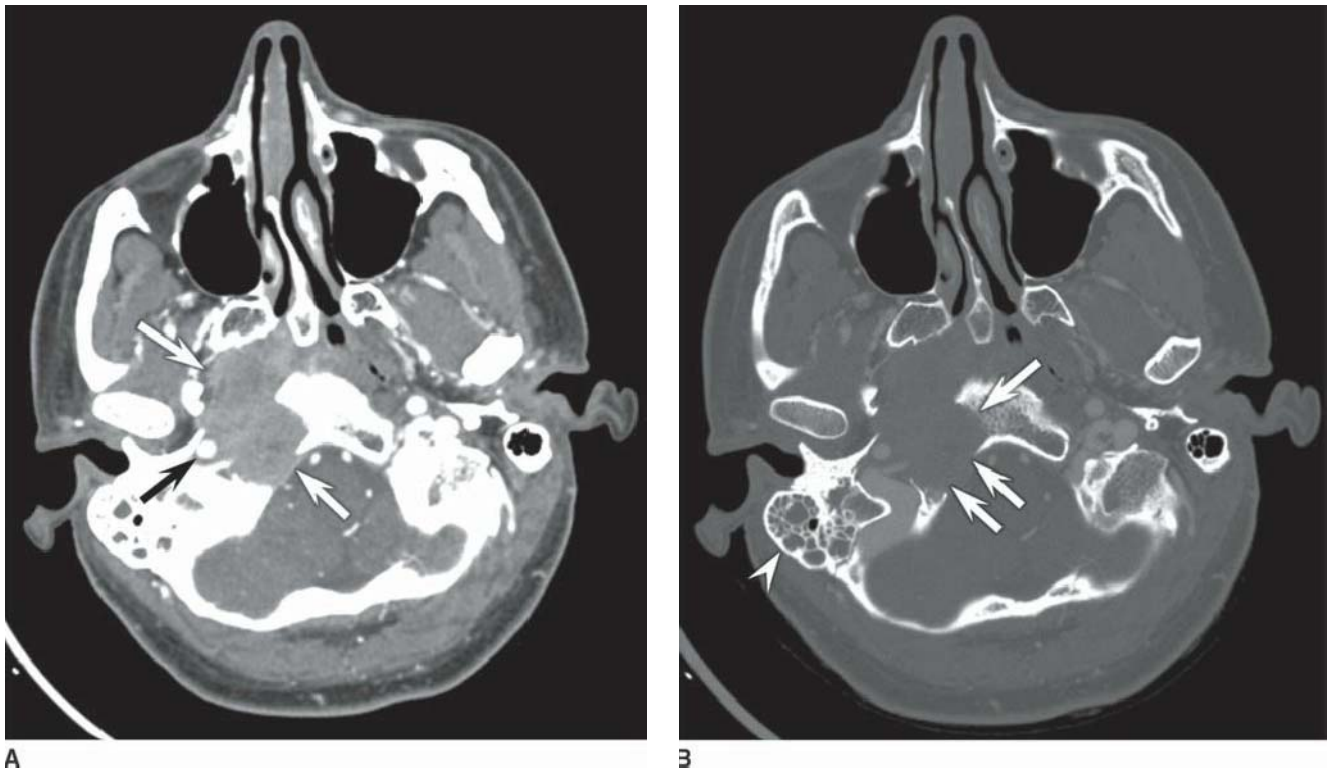

Figure 11.1 Nasopharyngeal carcinoma. **A:** Axial contrast-enhanced neck CT. The large right enhancing nasopharyngeal mass (*white arrows*) and its relationship to the right ICA (*black arrow*) along the posterolateral margin of the mass is best seen on the soft tissue windows. **B:** Bone windows at the same level better demonstrate erosion of part of the clivus and the right hypoglossal canal (*arrows*). The right mastoid effusion (*arrowhead*) from eustachian tube dysfunction is also better seen.

and intracranial compartment for complications related to otomastoiditis. It may also be useful in the evaluation of tumors involving the temporal bone, particularly if MRI is contraindicated.

Central Skull Base

Skull base CT technique is similar to the temporal bone in that it is typically performed without contrast and displayed in high-resolution bone algorithm with axial, sagittal, and

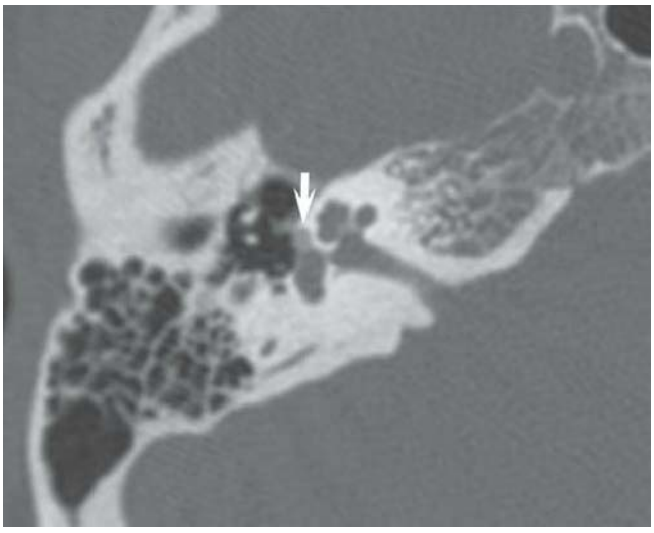

Figure 11.2 Fenestral otosclerosis (otospongiosis). Axial temporal bone CT. The thin-cut high-resolution bone algorithm technique nicely demonstrates demineralization (*arrow*) anterior to the oval window in the fissula ante fenestram, characteristic of fenestral otosclerosis.

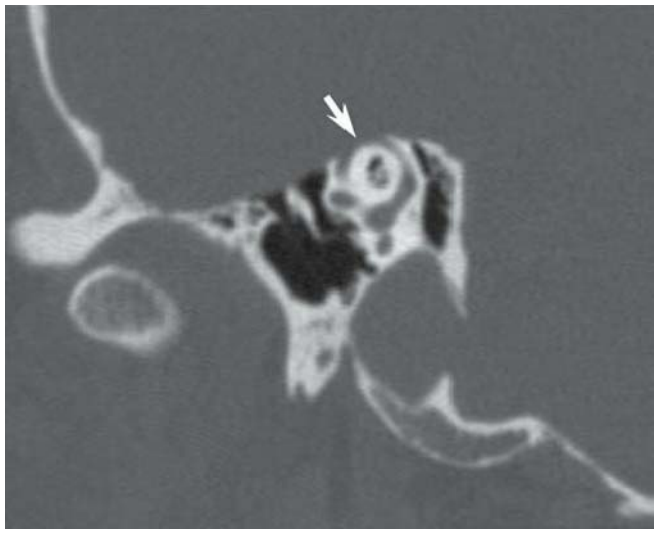

Figure 11.3 Superior semicircular canal dehiscence. A sagittal oblique reformatted image in the Pöschl plane parallel to the superior semicircular canal clearly demonstrates dehiscence of the bone (*arrow*) overlying the roof of the superior semicircular canal.

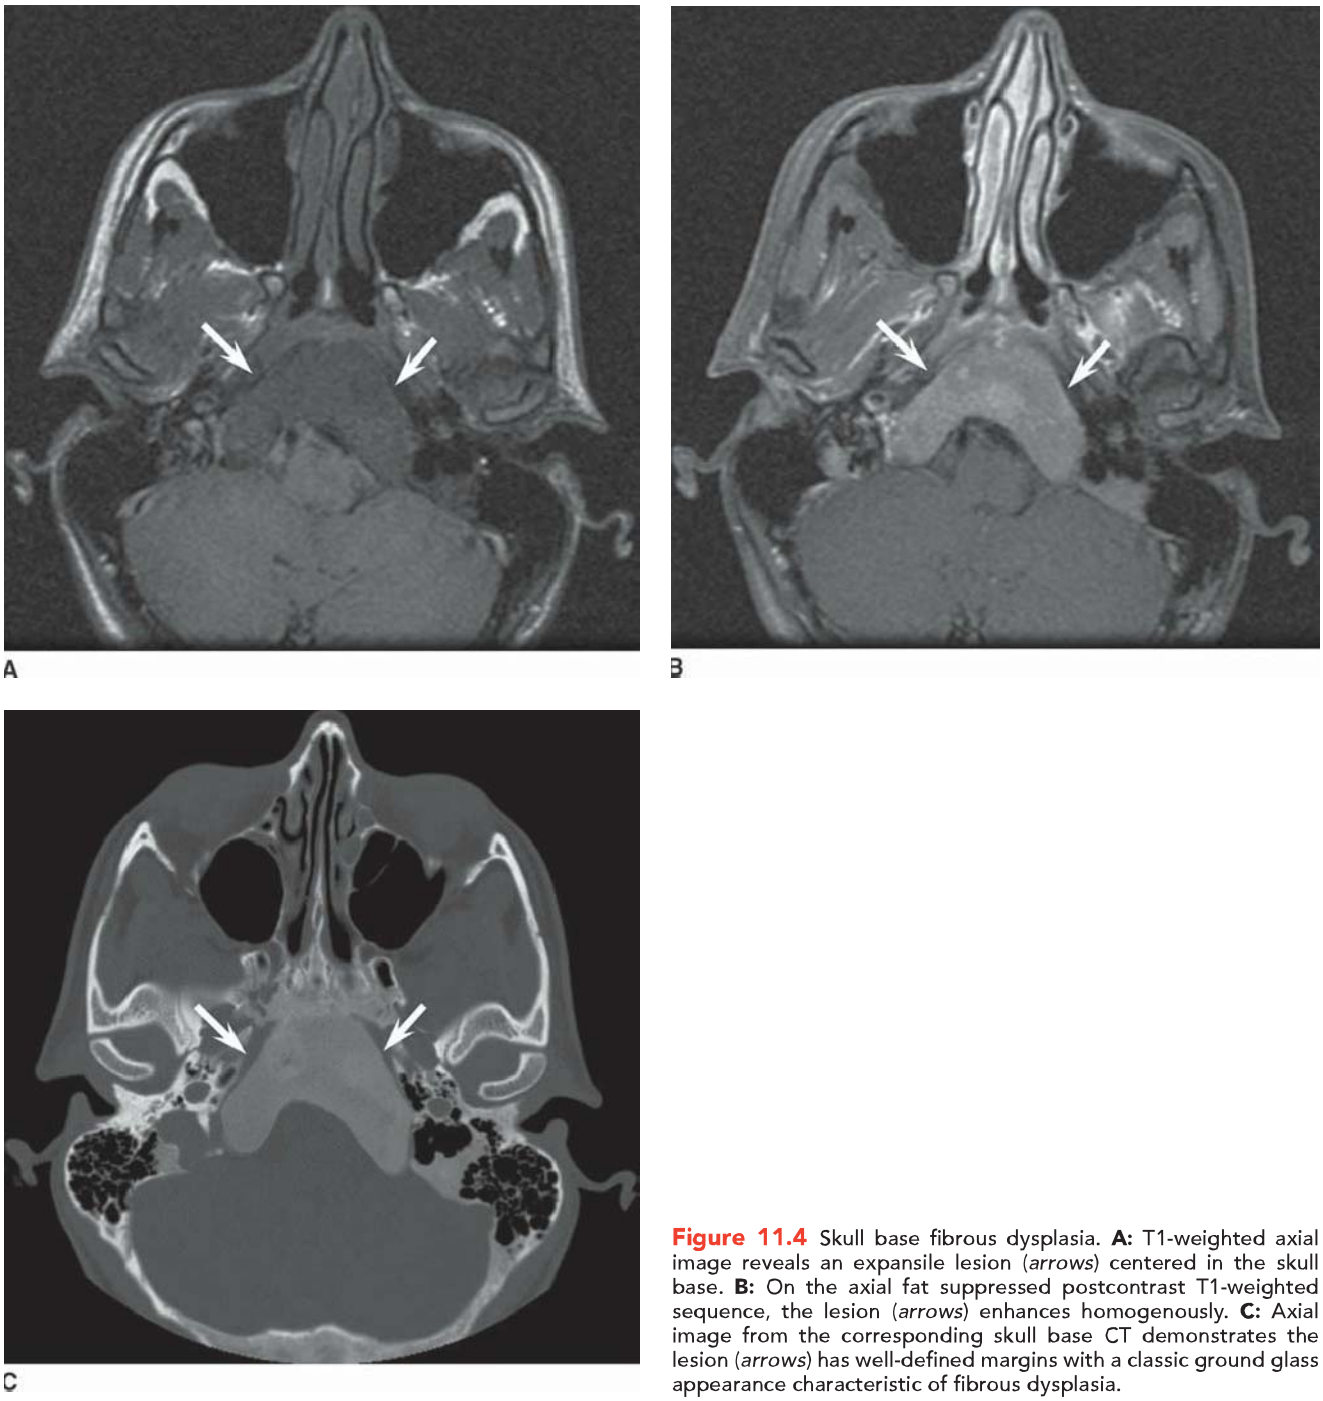

Figure 11.4 Skull base fibrous dysplasia. **A:** T1-weighted axial image reveals an expansile lesion (*arrows*) centered in the skull base. **B:** On the axial fat suppressed postcontrast T1-weighted sequence, the lesion (*arrows*) enhances homogenously. **C:** Axial image from the corresponding skull base CT demonstrates the lesion (*arrows*) has well-defined margins with a classic ground glass appearance characteristic of fibrous dysplasia.

coronal reconstructions using a typical slice thickness of 1.25 mm. However, the field of view is larger, focused on the central skull base, including the basiocciput and the sphenoid bone. The main indications for skull base CT include evaluation of fractures, dysplasias, primary bone lesions of the skull base, and secondary neoplastic involvement of the skull base. It nicely demonstrates the characteristic "ground-glass" appearance of fibrous dysplasia. This is particularly useful when fibrous dysplasia is incidentally found on MRI where it can be easily mistaken for a skull base tumor due to its variable signal characteristics and enhancement pattern (Fig. 11.4). CT evaluates the osseous integrity of the skull base and skull base foramina affected by neoplastic processes including but not limited to nasopharyngeal carcinoma, pituitary lesions, chordoma, chondrosarcoma, meningioma, Langerhans cell histiocytosis, metastasis, and myeloma. Enlargement or distortion of skull base foramina related to perineural spread of neoplasm can sometimes be appreciated, though direct imaging of perineural spread of neoplasm and intracranial extension is better demonstrated by MRI.

Maxillofacial Structures and Sinonasal Cavities

CT is the first study of choice to evaluate the osseous structures and adjacent soft tissues of the face and the sinonasal cavity, particularly in the setting of trauma or suspected inflammatory sinonasal disease. Normal anatomy and anatomic variations, mucosal disease and osseous integrity of the anterior skull base, and maxillofacial structures are well demonstrated.

Evaluation of the paranasal sinuses with plain film radiography has largely been replaced with CT. At some institutions, a screening sinus CT is performed to look for inflammatory disease with thick cuts in the axial or coronal plane performed at skip intervals with the technical parameters optimized for low-radiation exposure similar to plain films. This technique, however, does not well evaluate the anatomy and all walls of the sinonasal structures. It has fallen out of favor with the advent of helical multidetector CT and CT dose reduction strategies.

A high-resolution helical CT of the sinonasal structures is performed if detailed evaluation of maxillofacial trauma, sinus inflammatory disease, odontogenic disease, sinonasal neoplasm, or anatomy for presurgical planning is required. The widespread availability of helical multidetector CT precludes the previous need for direct coronal imaging to demonstrate the anterior ostiomeatal unit and replicate the endoscopic view of the paranasal sinuses. A typical protocol includes contiguous helical scanning with 1.25-mm-thick images obtained through the paranasal sinuses with multiplanar reformats created in the axial, sagittal, and coronal planes. The mandible can be included in the field of view if required. In the setting of trauma, three-dimensional (3-D) volume–rendered shaded surface display reconstructions can be helpful for planning craniofacial reconstruction, creating 3-D models and evaluating surgical results. Advantages of high-resolution helical imaging with multiplanar reformats include patient comfort, better demonstration of the anterior and posterior walls of the sinuses, and decreased motion and dental amalgam artifact. Contrast is not required for routine inflammatory sinus disease or trauma. In patients with acute odontogenic infection, contrast delineates associated soft tissue abscess and cellulitis. It can be helpful in defining the extent of sinonasal neoplasms or complications of sinusitis such as orbital cellulitis, subperiosteal abscess, or intracranial abscess (Fig. 11.5).

Orbit

Both CT and MRI are useful for evaluation of the orbit. CT is typically the initial study of choice when patients present to the emergency room with acute orbital symptoms. MRI is preferable if intracranial pathology or optic neuritis is suspected on the basis of clinical and physical exam. MRI better images the optic nerve and nerve sheath complex as well as the intracranial compartment, which can be affected when patients present with visual symptoms. Noncontrast CT is useful in cases of orbital trauma, evaluation of osseous orbital lesions, foreign body, calcifications, and thyroid orbitopathy (Fig. 11.6). In cases of acute

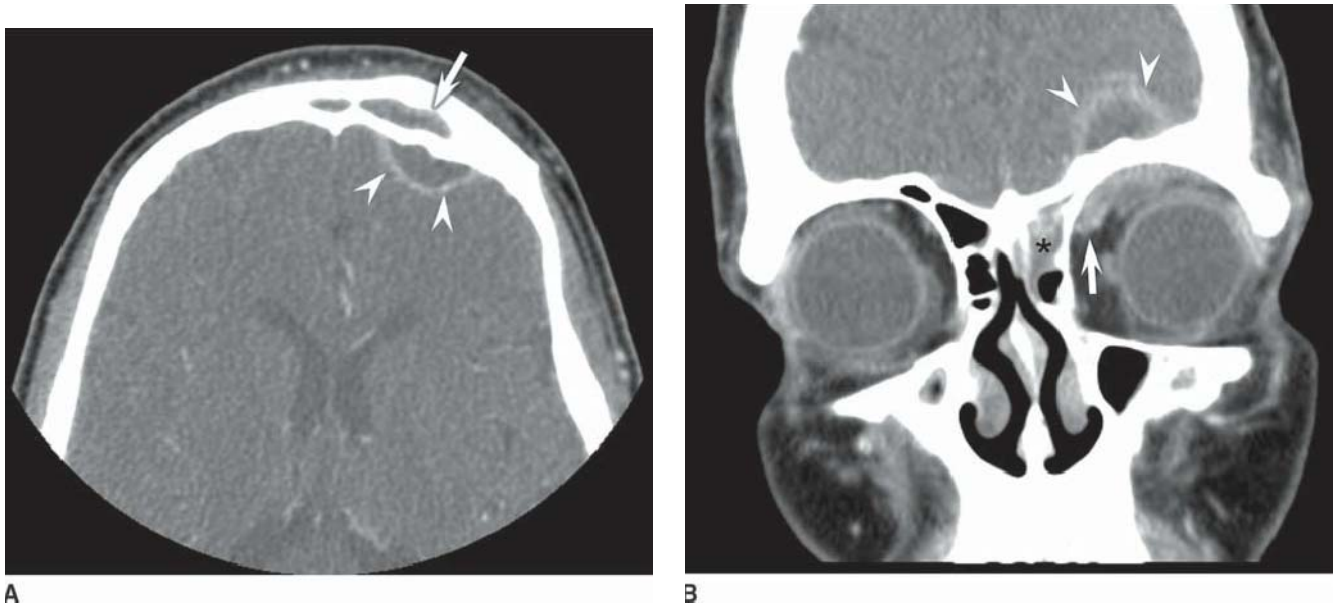

Figure 11.5 Intracranial abscess and orbital phlegmon as a complication of frontal sinusitis. **A:** Axial contrast enhanced maxillofacial CT. There is opacification of the left frontal sinus (*arrow*) due to sinusitis. The contrast nicely demonstrates the associated left frontal rim enhancing epidural abscess (*arrowheads*). **B:** Contrast-enhanced coronal CT reconstruction better demonstrates the associated phlegmon (*arrow*) in the superior left orbit as well as the left frontal epidural abscess (*arrowheads*). There is opacification of the adjacent left frontal sinus drainage pathway and ethmoid air cells (*asterisk*).

Figure 11.6 Thyroid orbitopathy. Coronal reconstruction from orbits CT without contrast. There is enlargement of all of the extraocular muscles bilaterally, typical of thyroid orbitopathy. The coronal reconstruction demonstrates the relationship of the extraocular muscles to the optic nerves (*arrows*).

orbital cellulitis, contrast-enhanced orbital CT is the first study of choice. Thin-cut images are obtained in the axial plane and reconstructed in the coronal and sagittal planes to better demonstrate the relationship of the optic nerve to the extraocular muscles.

Neck, Soft Tissues

A standard contrast-enhanced soft tissue neck CT evaluates the suprahyoid and infrahyoid soft tissues of the neck, including the aerodigestive tract, lymph nodes, glandular structures, and larynx. While soft tissue contrast is greater with MRI, contrast-enhanced CT is frequently the first study of choice in the evaluation of a neck mass or mucosal lesion of the upper aerodigestive tract because of its short acquisition time, universal availability, and reduced cost as compared to MRI. Generally speaking, neck CT is the preferred modality for evaluation of sialolithiasis, inflammatory neck processes, posttraumatic evaluation of the neck soft tissues, and evaluation of osseous cortex. There are few indications for noncontrast neck CT, including sialolithiasis, evaluation of patients with thyroid cancer who may require future treatment with radioactive I-131 and evaluation of neck pathology in patients with an absolute contraindication to IV administration of iodinated contrast. Contraindications to iodinated contrast administration include advanced renal insufficiency (not on dialysis), acute renal failure, and history of anaphylactic reaction to iodinated contrast. Patients with a history of milder allergic reactions to iodinated contrast should receive pretreatment with steroids to reduce the likelihood of a contrast reaction.

Good soft tissue contrast can be achieved with most lesions in the neck when iodinated contrast is administered and appropriate technique is employed with contrast present in both arteries and veins during the image acquisition. Contrast administration technique is critical to delineating the mucosal–submucosal interface, optimizing mucosal enhancement, and maximizing lesion detectability (Fig. 11.7). Using a helical scanner, 100 to 150 mL of contrast is administered via a power injector with an initial delay in image acquisition following the contrast injection to ensure adequate arterial and venous opacification. Exact protocols vary according to the scanner and institution. Scanning too early during the arterial phase may cause poor soft tissue contrast and lesion detectability, resulting in a false-negative study.

A routine contrast-enhanced neck CT typically extends from above the internal auditory canals caudally through the aortic arch, to include the course of the left recurrent laryngeal nerve (Fig. 11.8). Images are displayed at a slice thickness of 2 to 3 mm in the axial plane in both soft tissue and bone algorithm. In patients with dental amalgam or metal causing streak artifact, reangled images to avoid dental amalgam should be obtained because it can obscure pathology (Fig. 11.9). Coronal and sagittal reconstructions are commonly used to supplement axial images.

Modifications to a soft tissue neck CT protocol can be tailored to an area of interest or specific clinical question. In cases of a laryngeal mass, thin axial reconstructions through the larynx parallel to the laryngeal ventricle in bone and soft tissue algorithm are created to evaluate the extent of the lesion, paraglottic extension, and evidence of laryngeal cartilage erosion. Coronal reconstructions are helpful to evaluate for transglottic spread of tumor in the paraglottic space. At some institutions, additional images using the modified Valsalva maneuver (exhaling against a closed glottis or blowing through a straw) and phonation (patient exhales and makes the sound "eeee") are obtained, which dilates the laryngeal ventricle and pyriform sinuses in an attempt to better demonstrate the extent of tumor and anatomy. The added benefit of such techniques is controversial and must be weighed against added radiation exposure (5,6). In patients with a buccal mucosal lesion, a "puffed cheek" technique can be used to increase conspicuity of the lesion (7). If sialolithiasis is suspected, a noncontrast CT through the major salivary glands and oral cavity can be performed to evaluate for radio-opaque sialoliths that can be obscured by iodinated contrast. This can be followed by a routine contrast-enhanced neck CT in patients with clinical evidence of acute sialoadenitis. A good clinical history and communication between the referring clinician and radiologist is required to ensure that the protocol is tailored to answer the clinical question.

Neck, CT Angiogram

Helical multidetector CT angiography (CTA) has revolutionized vascular imaging in the past decade. Conventional angiography is still considered the "gold standard" for evaluation of vascular injury and vascular anatomy, but it has significant disadvantages including lengthy procedure, cost, and invasiveness with numerous risks including

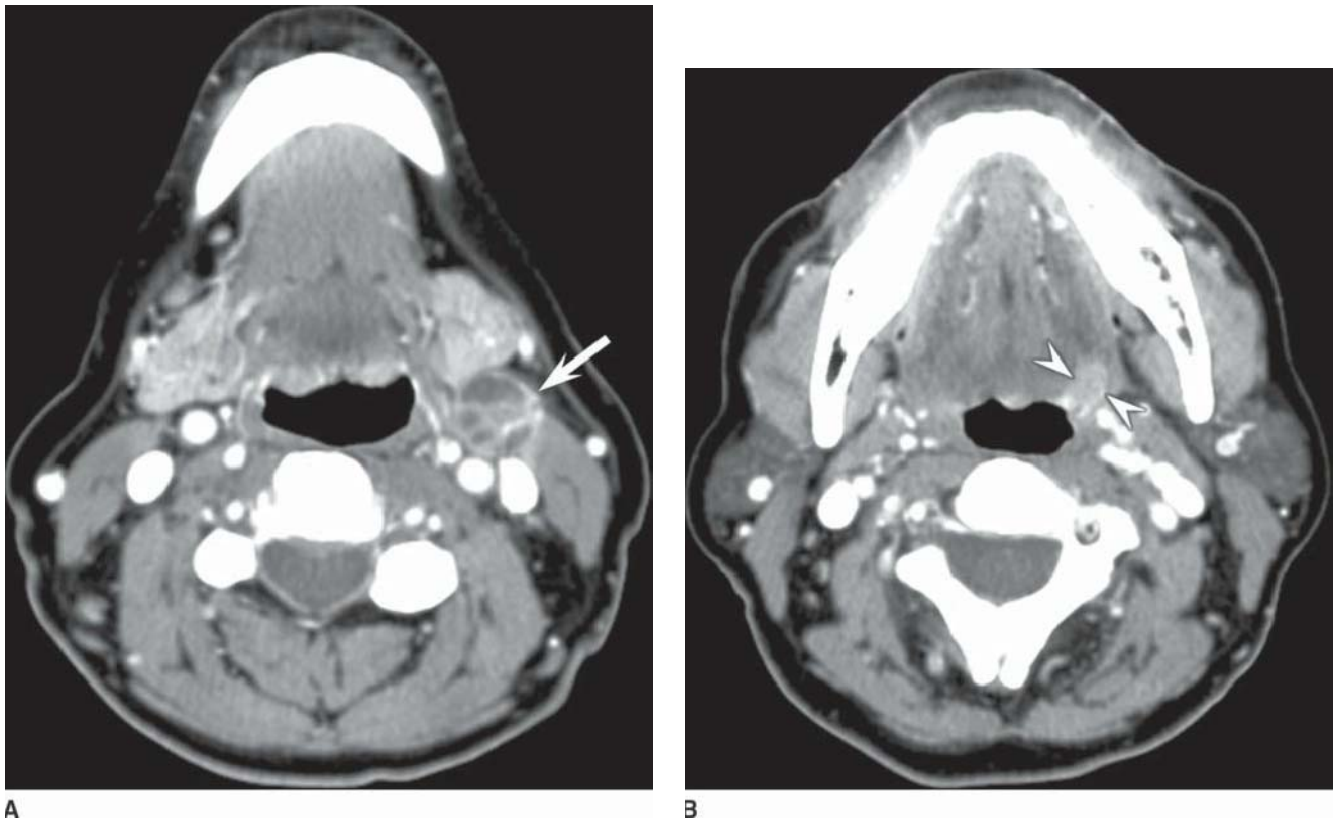

Figure 11.7 Left base of tongue squamous cell carcinoma with a metastatic left level II lymph node in a patient presenting with a palpable left neck mass. **A:** Axial contrast enhanced neck CT. The palpable mass is a malignant necrotic appearing left level II lymph node (*arrow*). **B:** Good contrast enhancement reveals the cause is an enhancing small left base of tongue squamous cell carcinoma (*arrowheads*).

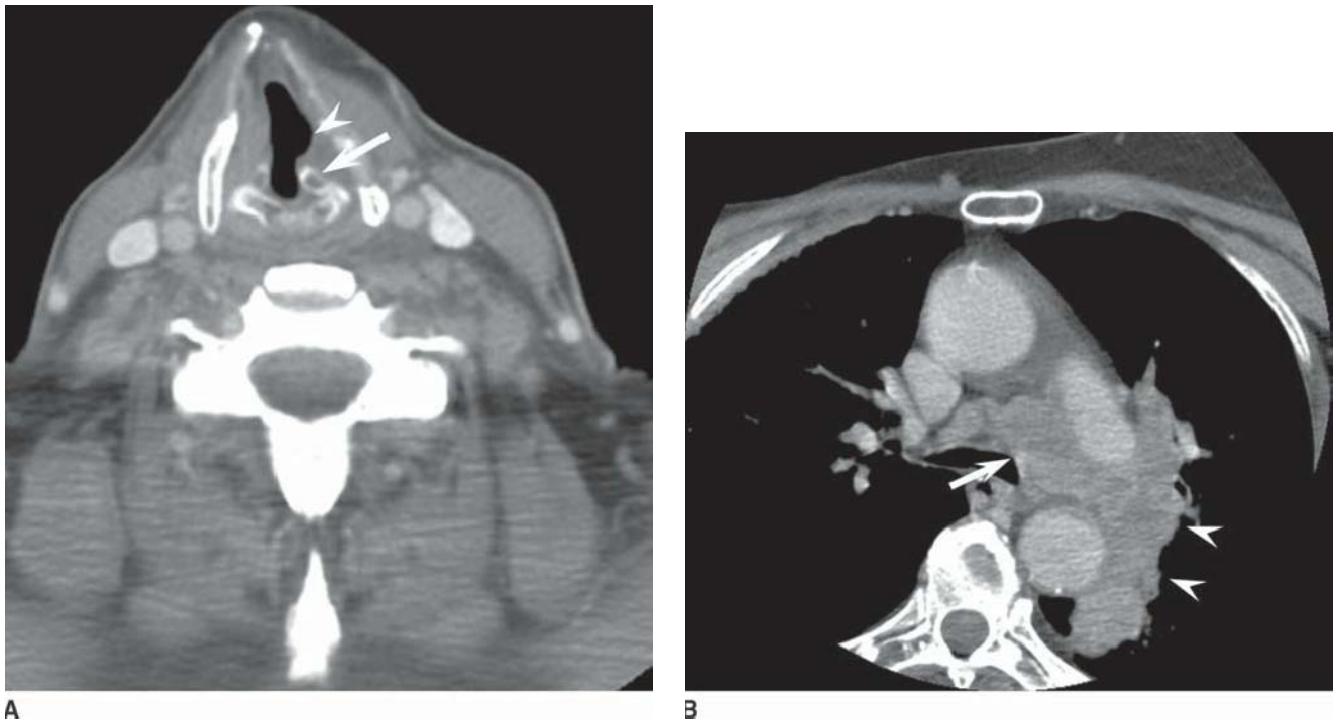

Figure 11.8 Aortopulmonary (AP) window metastatic lymphadenopathy and left hilar lung neoplasm in a 68-year-old male presenting with hoarseness and left vocal cord paralysis. **A:** Axial contrast-enhanced neck CT. The left arytenoid cartilage (*arrow*) is rotated and there is associated dilation of the left laryngeal ventricle (*arrowhead*), consistent with the patient's left vocal cord paralysis. **B:** Contrast-enhanced image from the neck CT extending through the superior mediastinum reveals the cause is a large left AP window nodal metastasis (*arrow*) from a left hilar lung neoplasm (*arrowheads*).

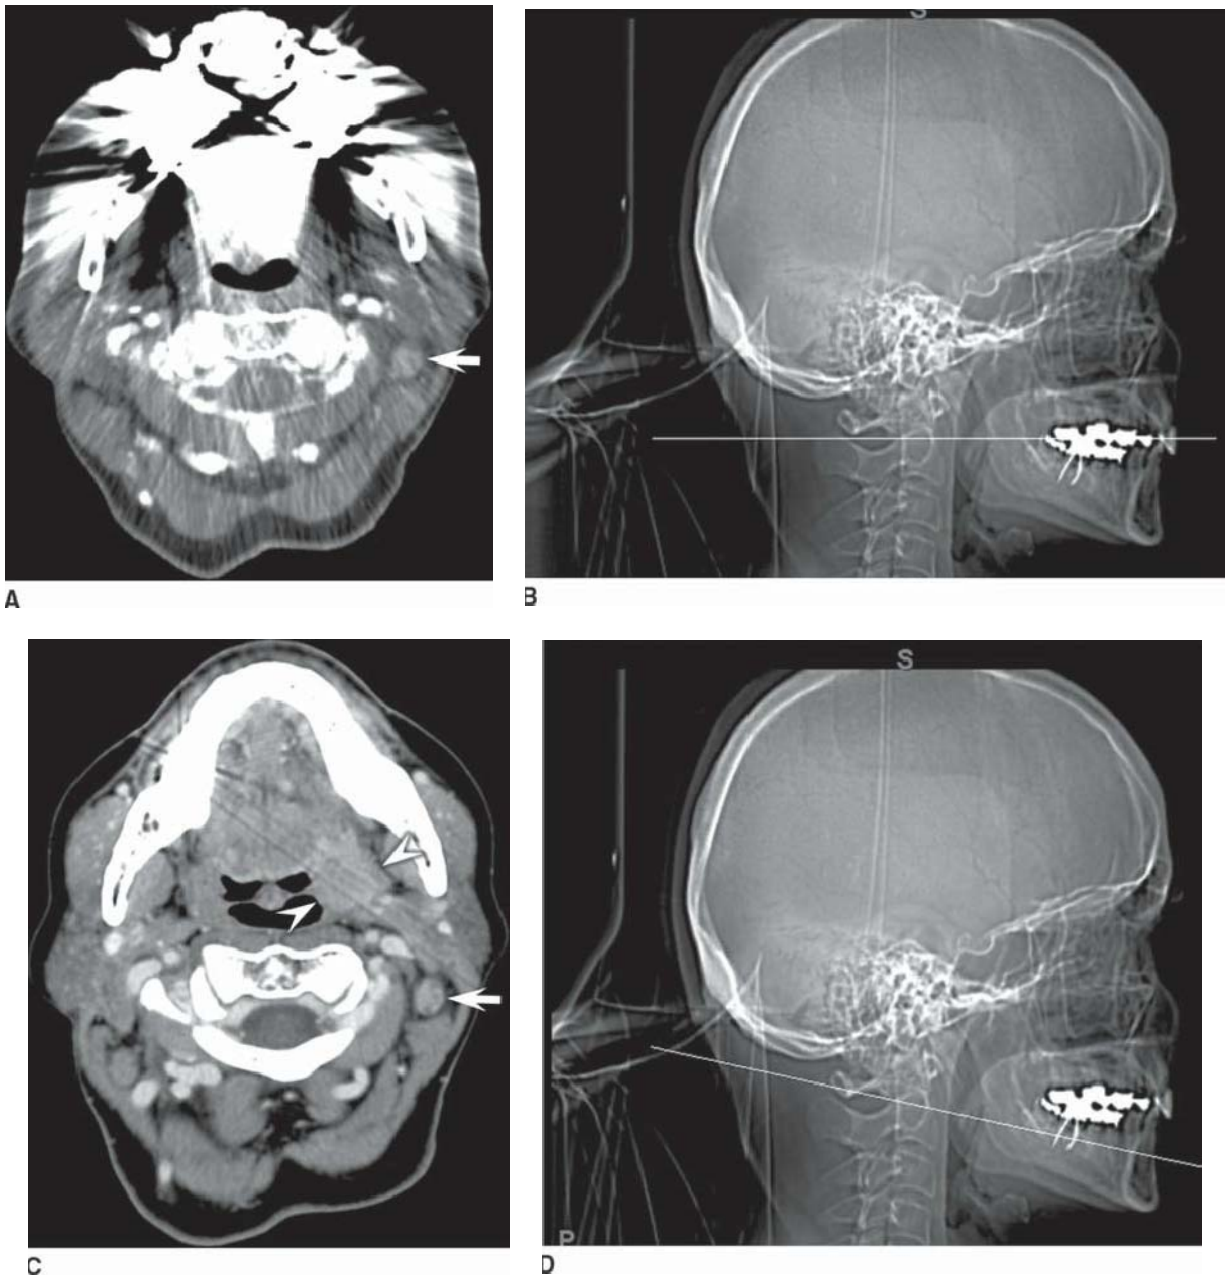

Figure 11.9 Left faucial tonsil carcinoma. **A,B:** Axial contrast-enhanced neck CT and corresponding scout view with a localizer line indicating the standard plane of imaging. **A:** Extensive streak artifact from dental amalgam completely obscures the oral cavity and portions of the oropharynx. An abnormal faucial tonsil mass is not demonstrated. The metastatic left level II lymph node (*arrow*) is poorly imaged due to the streak artifact. **B:** The plane of imaging indicated by the line courses directly through the patient's dental amalgam. **C, D:** Reangled contrast-enhanced axial CT from the same patient and corresponding scout view with a localizer line indicating the reangled plane of imaging. **C:** The large left faucial tonsil squamous cell carcinoma (*arrowheads*) extending into the left parapharyngeal fat and glossotonsillar sulcus is now clearly visible. Areas of low attenuation early necrosis in the enhancing metastatic left level II lymph node (*arrow*) are better demonstrated. **D:** The reangled plane of imaging indicated by the line avoids the dental amalgam.

dissection and stroke. Because of its accessibility, speed, and noninvasiveness, CTA is commonly used as a screening tool for vascular injury in patients with a history of blunt and penetrating neck trauma (8,9). CTA is also the primary imaging modality at many institutions prior to carotid endarterectomy. Conventional angiography is largely reserved for equivocal cases or cases requiring percutaneous intervention. CTA is best performed on a MDCT scanner (at least 16-slice or greater) using very thin cuts (e.g., 0.5-mm collimation) following the administration of iodinated contrast. Data are obtained from the thoracic aortic arch through the skull base. Multiplanar reformats are created

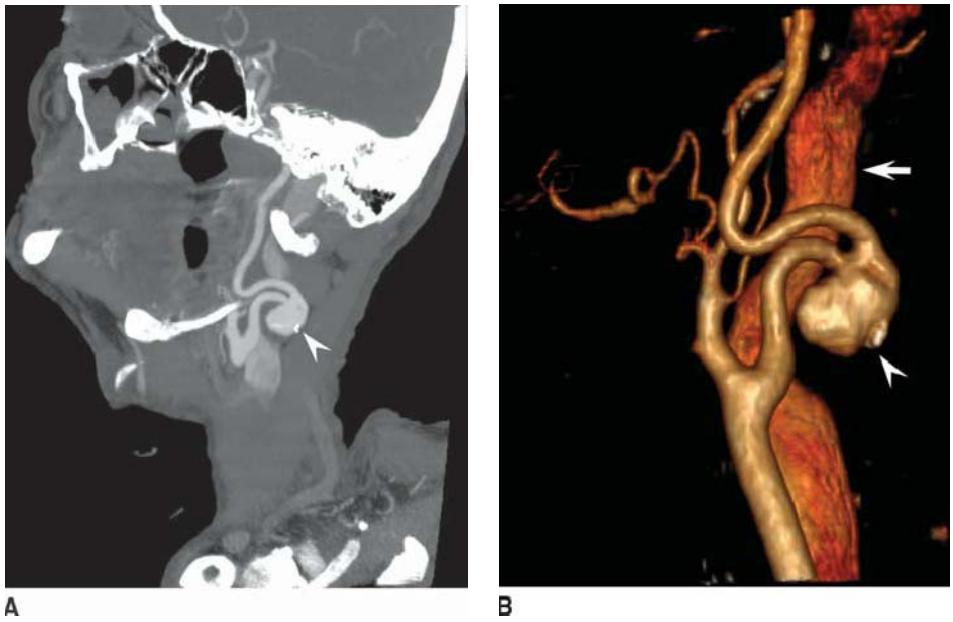

Figure 11.10 Right internal carotid artery (ICA) pseudoaneurysm in a 73-year-old male complaining of palpable right neck mass. **A:** Sagittal oblique reconstruction from contrast-enhanced CTA neck. There is a large saccular pseudoaneurysm (*arrowhead*) arising from the mid cervical right ICA projecting posteriorly. A small calcification in the pseudoaneurysm indicates it is chronic. **B:** 3-D volume-rendered shaded surface display reconstruction provides a better 3-D depiction of the pseudoaneurysm (*arrowhead*) directed posteriorly. The right internal jugular vein (*arrow*) is seen lateral to the right ICA.

and ideally 3D volume rendered reconstructions should be created by the interpreting radiologist because essential data can be lost during the postprocessing (Fig. 11.10).

MAGNETIC RESONANCE IMAGING

Imaging Principles

When a patient is placed in a strong magnetic field, the protons within the soft tissues of the body align with the field. To create an MR image, a radiofrequency pulse is applied that displaces the protons from alignment with the magnetic field. When the pulse is terminated, the displaced protons release a radiofrequency signal as they realign with the applied magnetic field. A receiving coil detects the signal emitted from the protons in the patient's tissues and spatially localizes it using gradient magnetic fields. A computer then applies complex mathematical algorithms to reconstruct the radiosignals into a final image. The appearance of the soft tissue contrast can be manipulated by changing the pulse sequence parameters. Most clinical MRI units use a field strength of 1.5 tesla (T) or 3 T. Lower field strengths are more commonly employed in open bore magnets. The greater the field strength, the better the signal-to-noise ratio, which can result in better image quality and/or throughput, although artifacts may be greater on 3 T units.

Technical advantages of MRI include good soft tissue contrast, multiplanar imaging capabilities, and lack of ionizing radiation. Disadvantages include motion artifact, pulsation artifact (from physiologic vascular motion and swallowing), and metal artifact. The longer the pulse sequence or overall time of the study, the greater the motion artifact. Voluntary swallowing and heavy breathing can cause substantial motion artifact. This can be particularly problematic in dyspneic patients with laryngeal pathology or chronic obstructive pulmonary disease. Dental amalgam artifact varies with the type and extent of amalgam, the scanner strength, and the sequences employed. There are also numerous contraindications including cardiac pacemaker, cochlear implant, metallic orbital foreign body, and ferromagnetic aneurysm clips, to name a few. Manufacturer recommendations regarding MRI safety for implanted medical devices must be sought before placing a patient in the scanner. Careful use of gadolinium-based contrast in patients with renal insufficiency must be employed due to the small but increased risk of developing nephrogenic systemic fibrosis (a systemic disease characterized by progressive multiorgan fibrosis following exposure to gadolinium-based contrast agents) in this population (10,11). Gadolinium use is contraindicated in pregnant patients.

Technical Considerations

Judicious use of MRI is required because of the relatively greater cost, reduced availability, and longer scan times as compared to CT. Scan time particularly influences image quality and excessively long imaging protocols or inappropriate use of MRI as a screening modality frequently results in motion degraded images with loss of diagnostic information. It is often complimentary to CT in the evaluation of head and neck pathology and protocols are usually focused to answer a specific clinical question (12).

Useful applications of MRI include evaluation of skull base pathology, perineural spread of neoplasm, neoplastic marrow space involvement, neoplastic cartilage invasion in the larynx and evaluation of oral cavity pathology, particularly when compromised by dental amalgam artifact on CT. Furthermore, when ultrasound is not adequate, MRI is the preferred modality in pediatric imaging to minimize radiation exposure in this population.

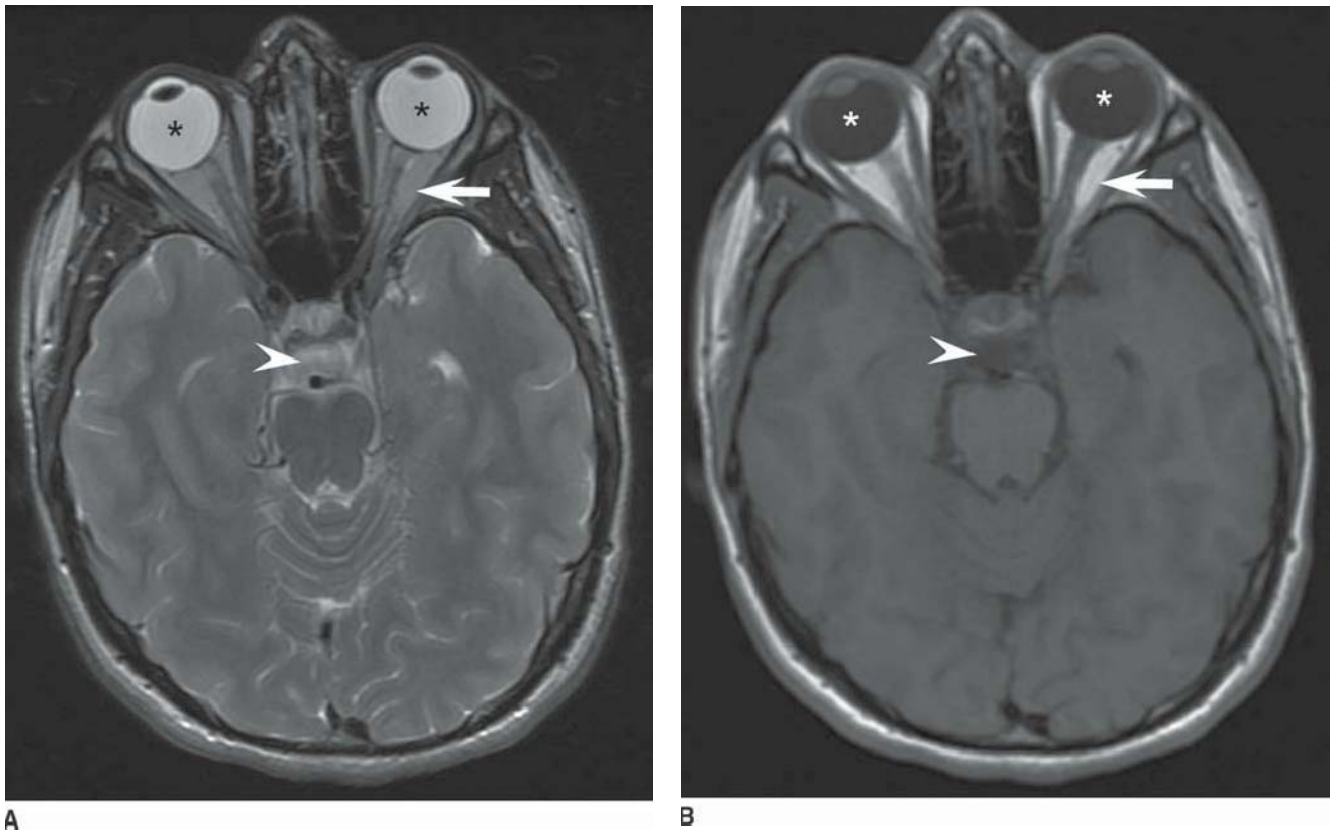

Figure 11.11 Normal brain MRI. **A:** Axial-T2 weighted image. Simple fluid is bright (*white*) signal as can be seen in the vitreous (*asterisk*) and in the normal CSF of the prepontine cistern (*arrowhead*). **B:** Axial T1-weighted image. Simple fluid in the vitreous (*asterisk*) and CSF of the prepontine cistern (*arrowhead*) are dark signal. **A** and **B:** Fat, as is seen in the orbits (*arrows*), is bright signal on both sequences.

Most basic MRI protocols of the neck and/or skull base include axial and coronal T1-weighted pre- and postcontrast images and T2-weighted sequences. T1-weighted images provide good anatomic detail and soft tissue contrast. On T1-weighted sequences, fat is high signal intensity, displayed as bright/white. Fluid, including normal cerebrospinal fluid (CSF) and vitreous, is low signal intensity, displayed as dark/black. On T2-weighted fast spin-echo (FSE) images, the most commonly employed T2-weighted sequence, CSF is displayed as bright/white signal and fat is also bright/white (Fig. 11.11). Muscle is intermediate on both T1- and T2-weighted sequences, displayed as gray. Contrast-enhanced T1-weighted images are used to delineate cystic from solid lesions.

Fat suppression techniques that null the bright/white fat signal are frequently applied to T2-weighted FSE and contrast enhanced T1-weighted sequences to improve tissue contrast of T2 hyperintense lesions and enhancing lesions surrounded by or distorting adjacent fat. Fat suppression techniques are also applied in orbital imaging where suppression of orbital fat signal increases conspicuity of orbital pathology, particularly evaluation of the optic nerves. The most common fat suppression techniques employed include short T1 inversion recovery (STIR) in which fat is placed at the null point of signal intensity and frequency selective presaturation spin-echo sequences in which fat signal is selectively suppressed (example sequences include T1-weighted postcontrast with fat suppression/fat saturation or T2-weighted with fat suppression/fat saturation) (Fig. 11.12).

Slice thickness varies from 3 to 5 mm. Focused thin section volumetric acquisitions can be employed to evaluate a specific area of interest such as the cavernous sinus or the facial nerve. The slice thickness is limited by the sequences employed. Unlike CT, imaging the entire neck from the skull base through the superior mediastinum typically requires two separate acquisitions. Additional sequences can be added to protocols in order to evaluate specific structures or answer-specific clinical questions as described in the following section.

Applications and Special Considerations by Region of Interest

Soft Tissue Neck, Aerodigestive Tract, and Larynx

For most pathology in the neck, CT is preferable to MRI because of its speed, accessibility, and lower cost. In the era of multidetector helical CT, the ability to create multiplanar reformats negates the traditional MRI advantage of multiplanar imaging capability. In many cases, the choice to use MRI versus CT in the evaluation

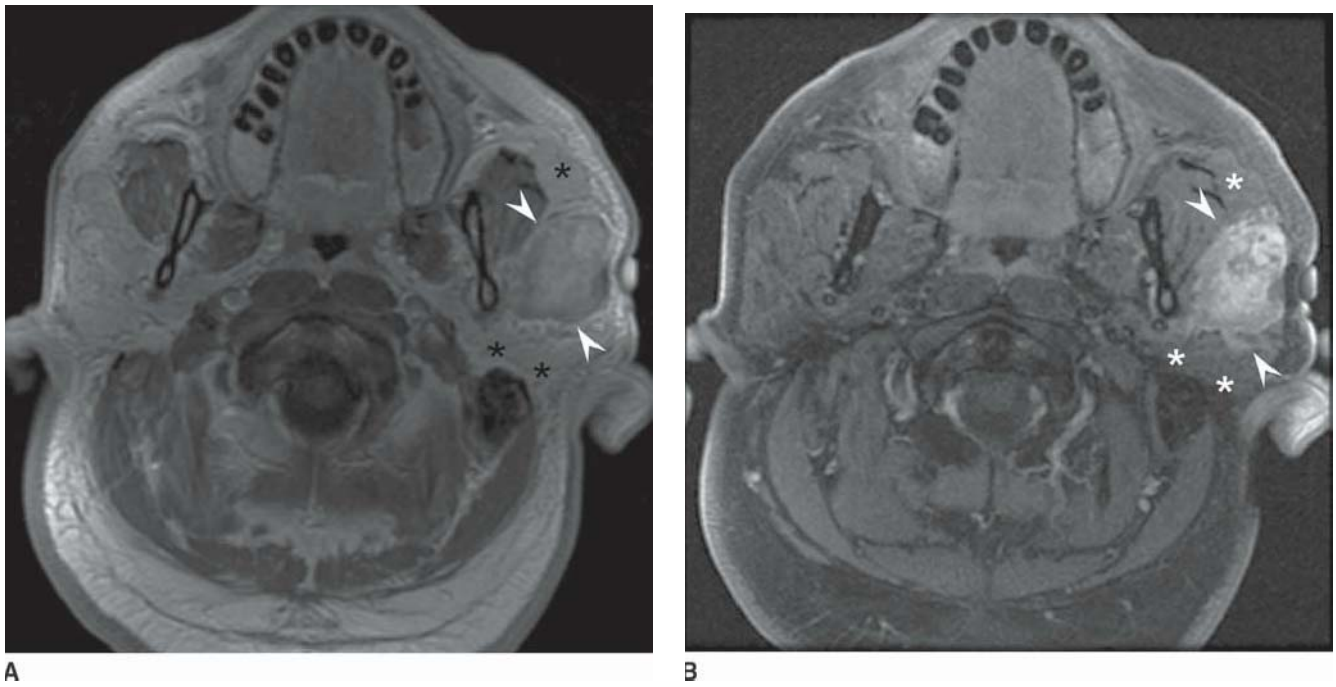

Figure 11.12 Left parotid carcinoma ex pleomorphic adenoma. **A:** Axial contrast-enhanced T1-weighted image. The large enhancing left parotid mass (*arrowheads*) is difficult to see because it has similar signal characteristics to the surrounding T1 hyperintense fatty parotid parenchyma (*asterisk*). **B:** Axial contrast-enhanced T1-weighted image with fat saturation. The same large enhancing left parotid mass (*arrowheads*) is much easier to see when soft tissue contrast is improved by suppressing the fat signal of the parotid parenchyma (*asterisk*), which is now displayed as dark signal.

of neck pathology is user preference or convenience though there are some instances where MRI offers distinct advantages.

In patients with laryngeal squamous cell carcinoma, MRI offers better soft tissue contrast and is more sensitive for the detection of cartilage invasion (13) (Fig. 11.13). Thin-cut or volumetric imaging to improve staging accuracy should be employed (14). With a high negative predictive value in the range of 94% to 96%, MRI is useful to exclude cartilage invasion. Unfortunately, MRI features of neoplastic cartilage invasion overlap with peritumoral inflammation, resulting in a less than optimal positive predictive value. Comparing the signal characteristics of the cartilage with the primary tumor may be helpful in improving specificity (15).

Additional useful applications of MRI in the head and neck include the following: evaluating cranial nerve palsies, excluding prevertebral invasion in patients with extensive mucosal space neoplasm, characterizing oral tongue and hard palate lesions, assessing oral cavity lesions obscured by dental amalgam, predicting resectability of squamous cell carcinoma involving the carotid artery, assessing preepiglottic fat invasion in head and neck neoplasms, and evaluating perineural spread of neoplasm associated with oral cavity and oropharyngeal tumors (16). While MRI is sensitive for the detection of mandibular marrow space involvement in patients with oral cavity and oropharyngeal cancer, it lacks specificity due to false positives from dental disease and sequela of radiation therapy (16). Traditionally, CT was considered more sensitive than MRI for the detection of nodal metastasis (17,18). With advances in MRI imaging, the sensitivity of MRI for detecting abnormal lymph nodes may be comparable to CT but for practical purposes, CT is the preferred modality for evaluating lymph node pathology in the neck (19,20). MRI should be reserved for problem solving or targeted imaging.

Temporal Bone

Patients presenting with facial nerve symptoms and adults presenting with sensorineural hearing loss are initially best evaluated with MRI. It evaluates for pathology affecting the brainstem (ischemic or demyelinating disease), the 7th and 8th cranial nerve complexes and the membranous labyrinth. Facial neuritis, schwannoma, hemangioma, and neoplastic processes affecting the 7th and 8th cranial nerves, inner ear and cerebellopontine angle are well demonstrated with high-resolution MRI.

Neoplastic, inflammatory, and infectious processes occurring in the petrous temporal bone frequently have a soft tissue component that affects the osseous integrity of the bone. MRI and CT are complimentary in evaluating such lesions. MRI characterizes the soft tissue component of the lesion and helps to differentiate inflammatory processes (petrous apicitis) or sequela of inflammatory processes

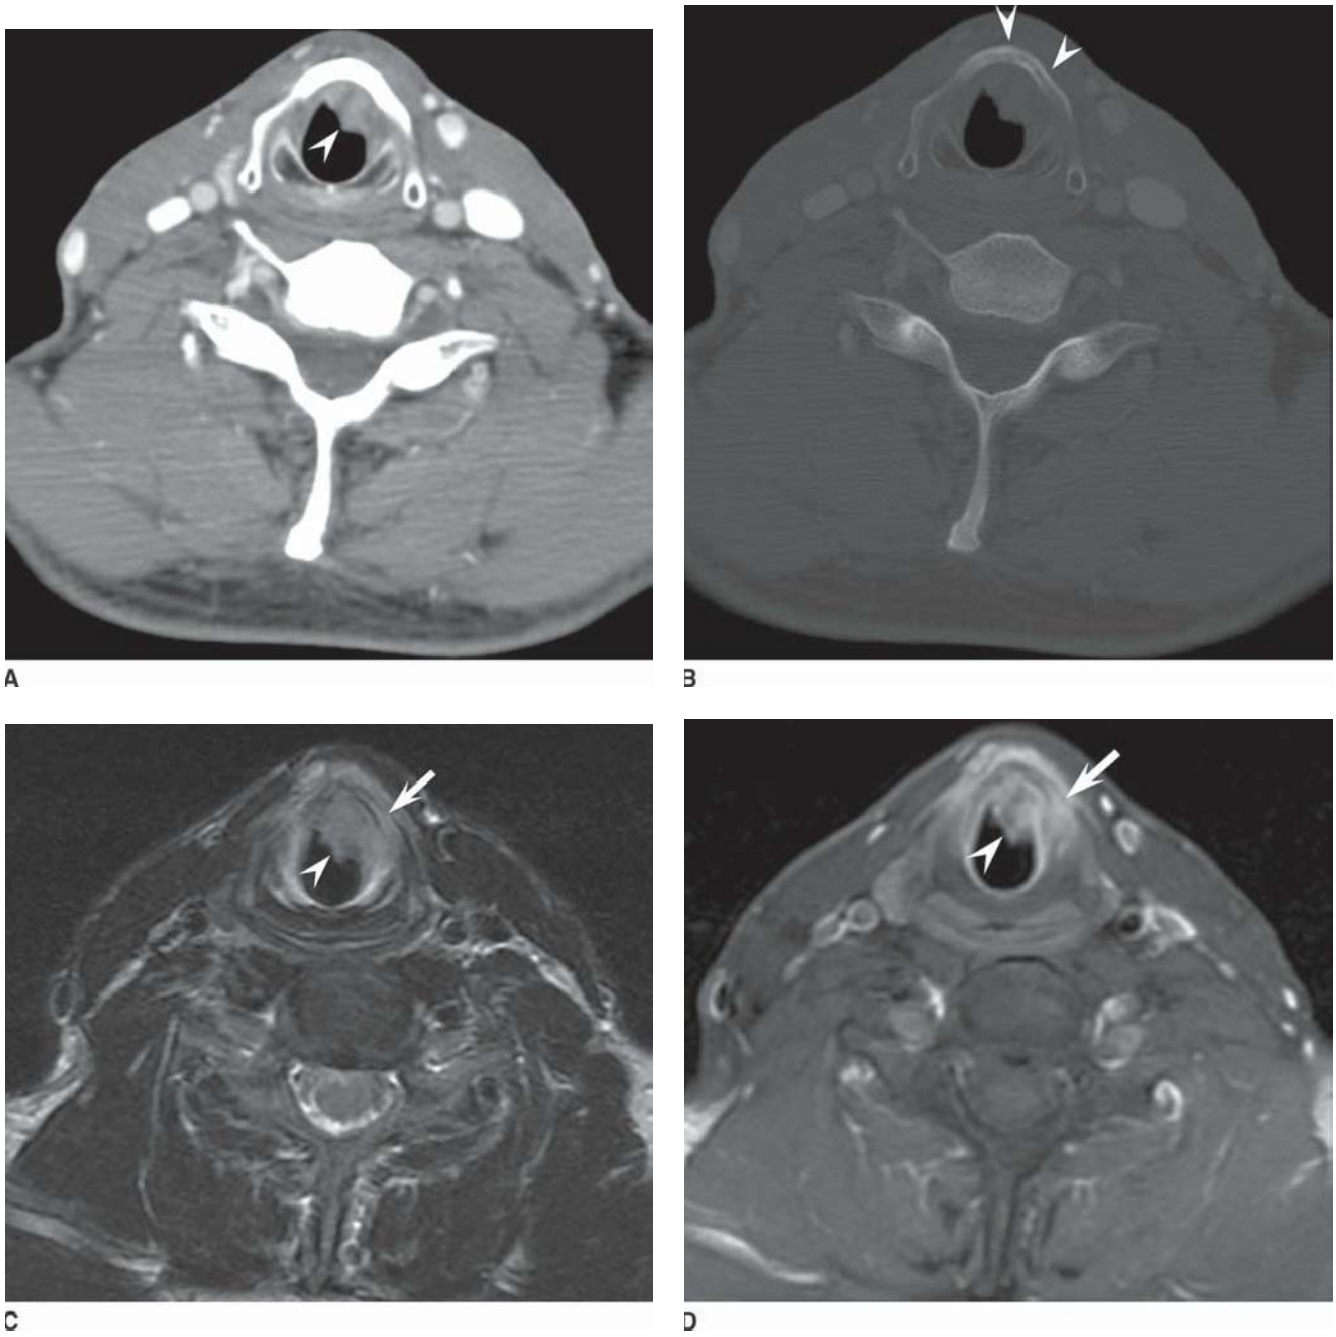

Figure 11.13 Laryngeal cartilage invasion from glottic squamous cell carcinoma with subglottic extension. **A,B:** Contrast-enhanced axial neck CT in soft tissue. **A:** There is tumor (*arrowhead*) within the subglottis anteriorly adjacent to the thyroid cartilage. **B:** On bone windows, there is no destruction or asymmetric sclerosis of the adjacent thyroid cartilage (*arrowheads*) to suggest thyroid cartilage invasion. **C:** Axial T2-weighted image reveals abnormal T2 hyperintense signal in the left anterior thyroid cartilage (*arrow*) similar to the tumor (*arrowhead*) in the subglottis. **D:** Contrast-enhanced axial T1-weighted image with fat suppression. There is associated enhancement in the left anterior thyroid cartilage (*arrow*) similar to the subglottic tumor (*arrowhead*), suggesting thyroid cartilage invasion. Neoplastic invasion of the thyroid cartilage was confirmed pathologically.

(cholesterol granuloma and mucocele) from neoplastic processes (metastasis, eosinophilic granuloma, chondrosarcoma). It also delineates the intracranial extent of disease and its effect on the adjacent brain parenchyma. CT better demonstrates associated osseous abnormalities.

Most temporal bone MRI protocols will include thin-cut precontrast T1-weighted images in the sagittal and axial planes to evaluate for high signal lesions and demonstrate anatomy. Contrast-enhanced T1-weighted images with fat suppression in the coronal and axial plane are used to look for enhancing lesions in the temporal bone or along the course of the 7th and 8th cranial nerve complexes. Various high-resolution T2 sequences (such as "CISS" or "FIESTA") can be used to delineate the 7th and 8th cranial nerves in their canalicular and cisternal segments where they appear dark against the background bright signal of the CSF resulting in a "cisternogram" effect (Fig. 11.14) (21–23). Many of the other cranial nerves, most notably the 5th cranial nerve, can be imaged in a similar manner. This technique can be useful to evaluate for tiny vestibular schwannomas (particularly if contrast is contraindicated) or compression of the 7th nerve root entry zone which can contribute to hemifacial spasm. Diffusion-weighted imaging can be useful in evaluation of petrous apex lesions and in postoperative temporal bone evaluation. Both epidermoid cyst of the petrous apex (congenital cholesteatoma) and recurrent acquired cholesteatoma in the postoperative temporal bone demonstrate high signal intensity compared to brain tissue on diffusion-weighted images. Recent research suggests nonecho planar-based diffusion-weighted sequences with thinner sections and decreased susceptibility artifacts are the most useful for helping distinguish scar tissue and granulation tissue from recurrent cholesteatoma in the postoperative temporal bone (24,25). In patients with dehiscence of the tegmen tympani or tegmen mastoideum, thin-cut high-resolution coronal T2-weighted images and contrast-enhanced T1-weighted images are used to evaluate for meningocele or encephalocele.

Nasopharynx and Skull Base

Imaging plays a critical role in the evaluation of the skull base and nasopharynx because this area is centrally located and difficult to evaluate clinically. Skull base pathology can be categorized into processes originating above the skull base, below the skull base, or centered within the skull base. Consequently, it is important to tailor imaging protocols to include the relevant adjacent intracranial compartment and/or extracranial soft tissues. The soft tissue component of skull base pathology and potential routes of perineural spread of aggressive neoplasms are best imaged with MRI (26,27). CT better demonstrates osseous erosion and matrix associated with lesions, so both modalities are often employed (Fig. 11.15).

In order to optimize evaluation for perineural spread of tumor, protocols should use a small field of view focused on the area of interest using thin-cut 3-mm slices. Possible routes of direct or perineural spread of neoplasm in the orbits, hard palate, pterygopalatine fossa, skull base foramina, cavernous sinus, and temporal bone extending back to

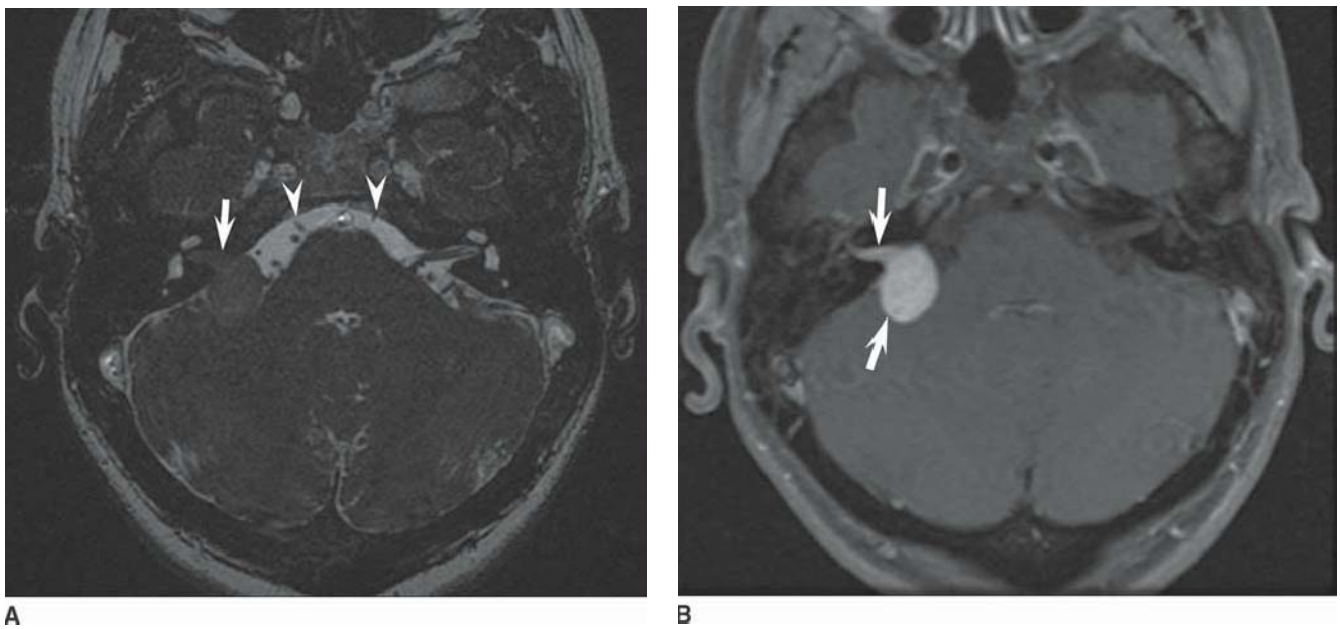

Figure 11.14 Right vestibular schwannoma. **A:** Axial FIESTA through the cerebellopontine angle. There is a large right vestibular schwannoma (*arrow*) filling the right internal auditory canal up to the fundus. It protrudes into the cerebellopontine angle and flattens the ventral margin of the right cerebellar hemisphere. The normal 7th and 8th cranial nerves are seen in the contralateral internal auditory canal. The 6th cranial nerves (*arrowheads*) are also seen in the prepontine cistern; the left 6th nerve is entering Dorello's canal. **B:** Axial contrast enhanced T1-weighted image with fat suppression. The right vestibular schwannoma (*arrows*) avidly enhances.

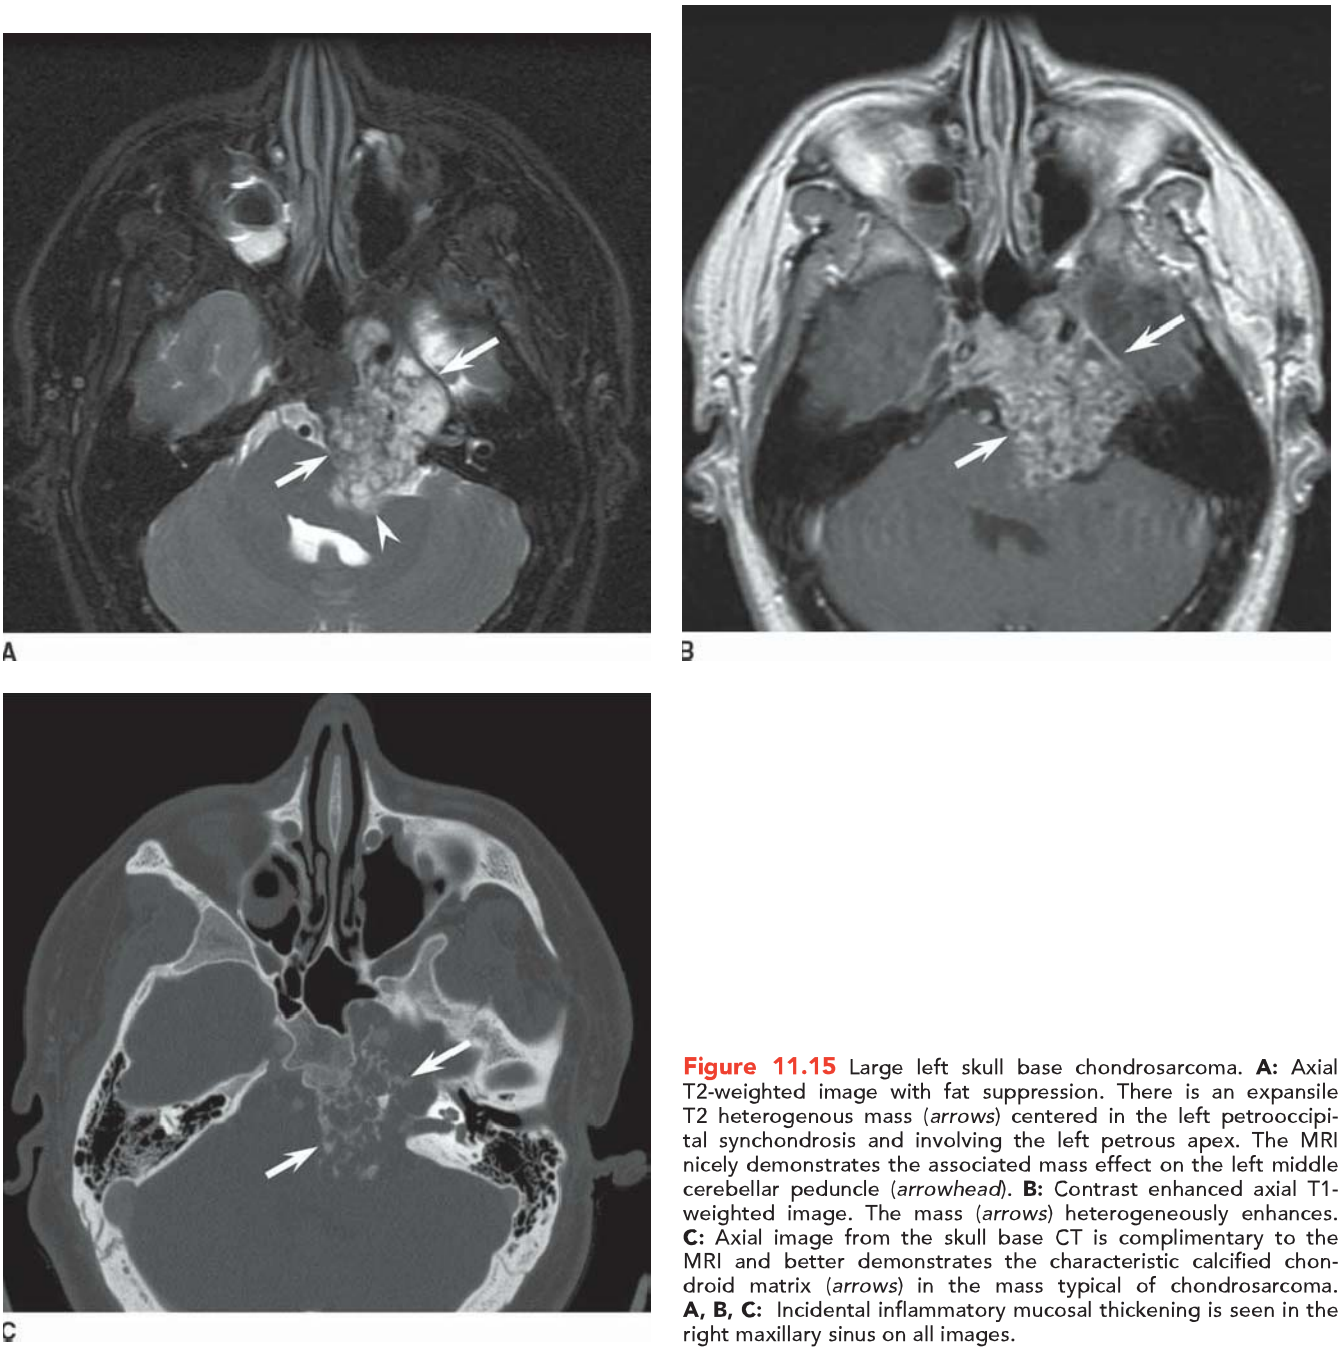

Figure 11.15 Large left skull base chondrosarcoma. **A:** Axial T2-weighted image with fat suppression. There is an expansile T2 heterogenous mass (*arrows*) centered in the left petrooccipital synchondrosis and involving the left petrous apex. The MRI nicely demonstrates the associated mass effect on the left middle cerebellar peduncle (*arrowhead*). **B:** Contrast enhanced axial T1-weighted image. The mass (*arrows*) heterogeneously enhances. **C:** Axial image from the skull base CT is complimentary to the MRI and better demonstrates the characteristic calcified chondroid matrix (*arrows*) in the mass typical of chondrosarcoma. **A, B, C:** Incidental inflammatory mucosal thickening is seen in the right maxillary sinus on all images.

the 5th and 7th nerve root entry zones should be imaged. Fat suppressed T1 postcontrast images are useful to directly image the nerves traversing the skull base to evaluate for excessive enhancement along nerve branches or widening within the pterygopalatine fossa, skull base foramina, Meckel's cave or cavernous sinus, all of which can be seen with perineural spread of neoplasm (Fig. 11.16). Thin-cut T1-weighted images without contrast are essential to evaluate for loss of the normal fat surrounding nerves in the pterygopalatine fossa, within the infratemporal fossa and as they enter neural and skull base foramina as this can also be a sign of perineural spread of tumor. In Adults, Axial T1-weighted images are important to evaluate for loss of the normal fatty skull base marrow signal, which can be seen with neoplastic marrow infiltration, skull base osteomyelitis, blood dyscrasias, and other primary bone lesions (28).

Paranasal Sinuses

CT and MRI are complimentary in the evaluation of sinonasal neoplasms (29). The main utility of MRI of the paranasal sinuses and maxillofacial structures is to evaluate the extent of sinonasal neoplasms and associated perineural spread of neoplasm that will influence surgical approach and treatment planning. MRI delineates the margins of the

mass from adjacent obstructed secretions and inflammatory mucosal disease. It directly images skull base invasion, perineural spread of neoplasm, intraorbital involvement and intracranial extension of neoplasm, including dural and brain parenchyma invasion. Similarly, in cases of invasive fungal disease, MRI better characterizes the intracranial and perineural spread of disease. CT evaluates the osseous integrity of the orbits, anterior skull base, and maxillofacial structures (Fig. 11.16). A protocol similar to the described skull base protocol should be used with the field of view tailored to include the relevant portions of the craniofacial structures, orbits, sinonasal cavity, skull base, and mandible.

Salivary Glands

MRI is the study of choice for evaluation of a painless salivary mass, particularly if it is accompanied by a cranial nerve deficit (30). It offers good special resolution with superior soft tissue contrast compared to CT. In patients with a suspected inflammatory or infectious process involving the salivary glands, CT is the preferred imaging modality because sialoliths are difficult to see with MRI.

Imaging should extend to the skull base and posterior fossa to include the course of 5th and 7th cranial nerves to adequately assess for extent of perineural spread of neoplasm. In adults, parotid masses are well delineated on T1-weighted images because of the fatty background of the gland, which serves as a natural contrast agent. The margins of a parotid mass including extension into the adjacent parapharyngeal fat, masticator space, and bone marrow are well delineated on this sequence. Fat suppressed contrast-enhanced T1-weighted images are used to distinguish cystic from solid masses and evaluate for perineural spread and marrow space invasion. Fat suppressed T2-weighted images can be helpful in suggesting a lesion is malignant as most high grade malignant neoplasms will have low to intermediate signal on T2-weighted images and most benign parotid masses are T2 hyperintense (Fig. 11.17). There is, however, overlap between the signal characteristics of benign and malignant lesions. Low grade mucoepidermoid and adenoid cystic carcinomas can be T2 hyperintense while benign Warthin tumors can be T2 intermediate or low signal. Imaging does not serve as a substitute for soft tissue sampling.

Orbits

MRI is frequently the study of choice for many neuro-ophthalmic conditions. It offers better soft tissue evaluation of the optic pathways, cavernous sinus region, sella turcica, and brain parenchyma, all of which can be affected when patients present with visual or neuro-ophthalmic symptoms. All orbital protocols should include imaging in two orthogonal planes, typically the axial and coronal plane to demonstrate the relationship of the extraocular muscles with the optic nerve, osseous orbital margins, and orbital apex. T1-weighted precontrast images should be included to evaluate for T1 hyperintense choroidal lesions, which can be seen with melanoma. Utilizing fat suppression when imaging the orbits is critical on T2 and contrast-enhanced T1-weighted sequences to increase tissue contrast of orbital mass lesions surrounded by fat in the orbit and detect optic nerve and nerve sheath enhancement (Fig. 11.18).

Many orbit protocols will include an axial fluid attenuated inversion recovery sequence of the brain to evaluate for any evidence of demyelinating disease, which supports a diagnosis of multiple sclerosis in patients with optic neuritis. Protocols can be modified to include MR angiogram, MR venogram, or MRI of the brain, skull base, or neck depending on the patient's clinical presentation (optic neuropathy, visual field deficit, cranial nerve deficit, optic disc swelling, Horner syndrome) and the suspected pathology (31).

Temporomandibular Joint

MRI is the preferred modality to evaluate for internal derangement in patients with temporomandibular joint (TMJ) dysfunction (32,33). Proton density or T1-weighted images may be used to demonstrate the margins of the disk relative to the joint capsule and bone (Fig. 11.19). Small field of view high-resolution imaging is employed. A typical protocol includes proton density coronal images and sagittal oblique images in closed and open mouth views. Open mouth images are used to evaluate disk function. Coronal images in the closed mouth view are used to look for medial or lateral displacement of the disc. T2-weighted images in the oblique sagittal closed mouth view are used to look for marrow edema and joint effusion.

Dynamic and pseudodynamic MRI of the TMJ has been the subject of research in an attempt to better characterize joint range of motion and to demonstrate pathology that may only be seen during mouth opening and closing (34–36). Image noise, suboptimal disc visualization, and temporal resolution remain barriers to the routine use of dynamic TMJ MRI at this time and the technique still requires validation. Currently, dynamic TMJ MRI may be used as an adjunct to standard open and closed mouth TMJ MRI but is not a replacement for it (34). CT is complimentary to MRI and provides good bone detail in cases of neoplastic involvement of the TMJ, posttraumatic deformity, and inflammatory arthropathy.

Brachial Plexus

Because it is inaccessible to direct palpation, clinical evaluation of the brachial plexus is challenging and imaging plays a critical role. MRI is well suited to evaluate the complex anatomy and pathology of the brachial plexus due to its multiplanar imaging capability and excellent soft tissue contrast. T1-weighted images demonstrate the anatomy best as the fat surrounding the brachial plexus acts as a natural contrast to delineate the roots, trunks, divisions, and cords. T2-weighted FSE images with fat suppression are used to identify pathologic signal changes in the plexus. Postcontrast images are useful when neoplasm, inflammation, infection, or stretch injury is suspected (37). The sagittal plane is particularly useful to evaluate

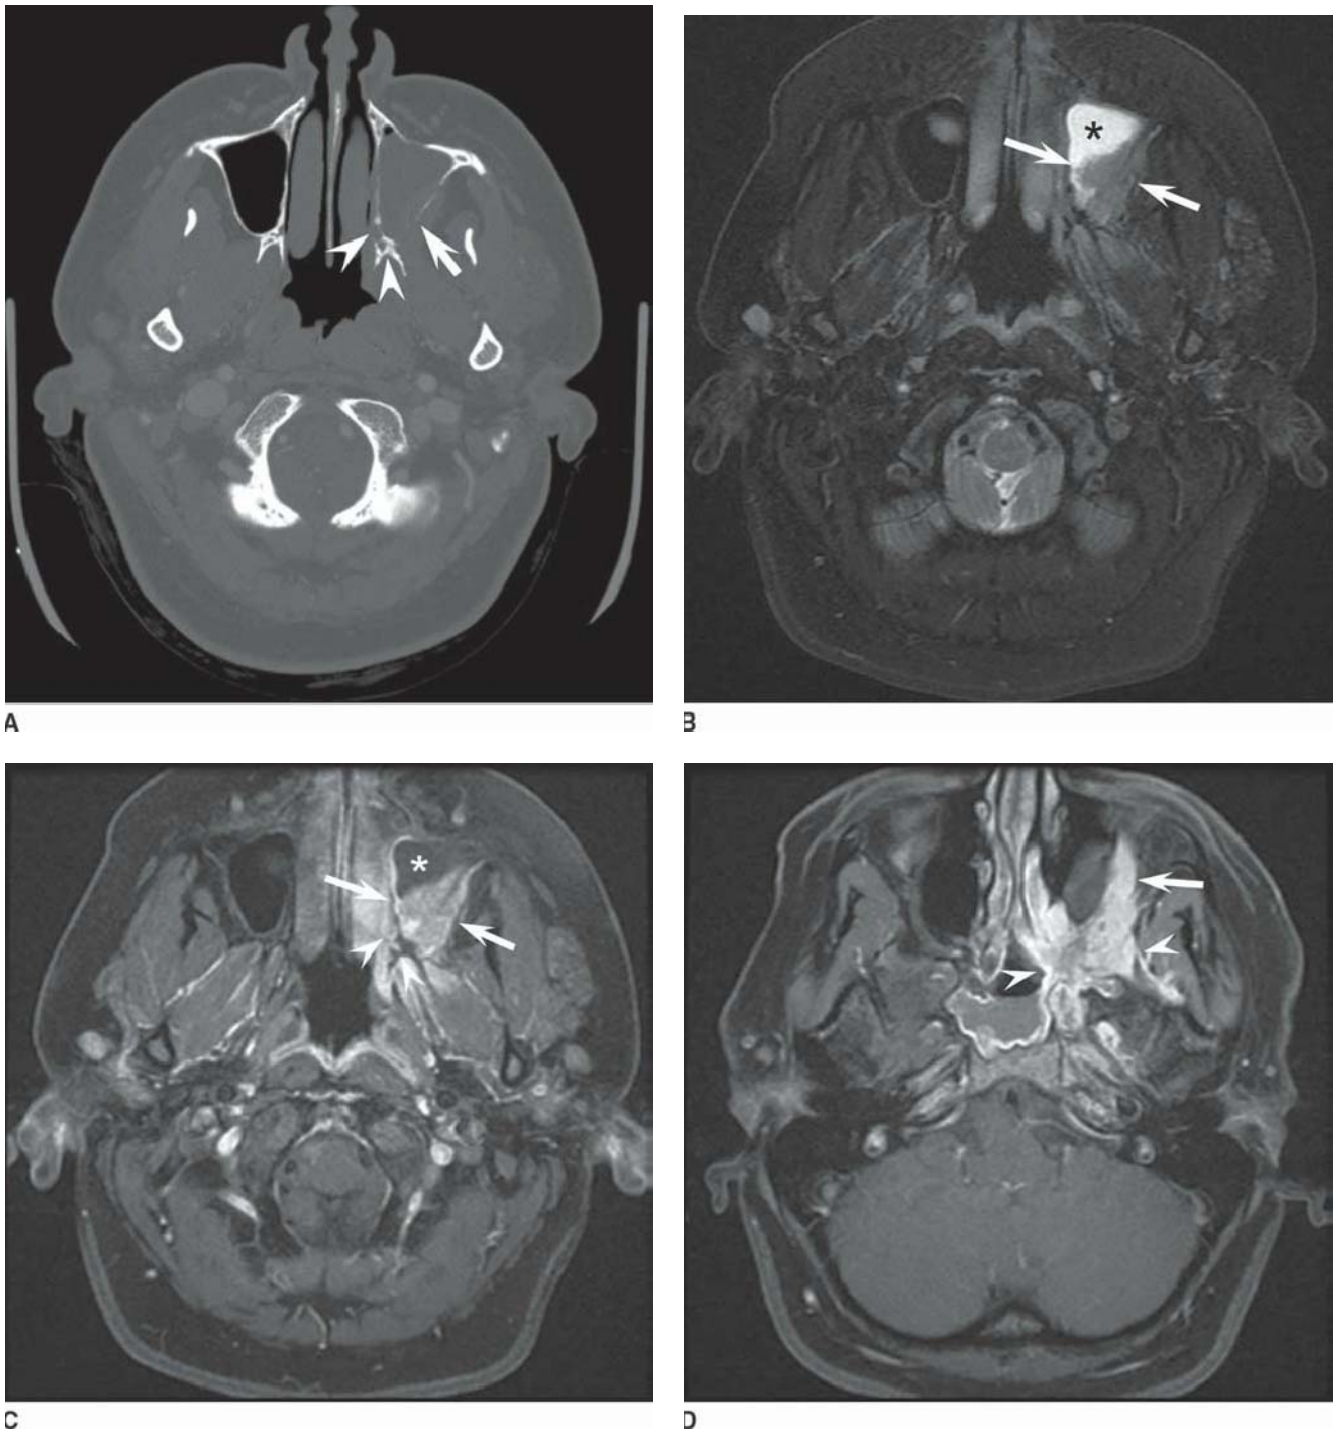

Figure 11.16 Adenoid cystic carcinoma in a 22-year-old female with left facial pain. **A:** Axial contrast-enhanced CT displayed in bone algorithm. There is complete opacification of the left maxillary sinus. Areas of erosion of the posterolateral wall of the left maxillary sinus (*arrow*) and widening of the left greater and lesser palatine foramina (*arrowheads*) suggest an underlying sinonasal neoplasm with perineural spread of tumor. **B:** Axial T2 with fat saturation. There is a T2 intermediate mass (*arrows*) in the dorsal aspect of the left maxillary sinus extending into the left retroantral fat. The mass is easily distinguished from inflammatory secretions (*asterisk*) within the anterior left maxillary sinus that are T2 hyperintense. **C–E**: Contrast-enhanced axial T1-weighted images with fat suppression. **C:** The mass (*arrows*) avidly enhances. The inflammatory secretions do not (*asterisk*). Enhancing perineural spread of tumor is seen in the enlarged left greater and lesser palatine foramina (*arrowheads*). **D:** There is extensive enhancing perineural spread of tumor along the markedly enlarged left infraorbital nerve (*arrow*) and within the left pterygopalatine fossa extending into the left pterygomaxillary fissure (*arrowheads*). There is incidental inflammatory opacification in the right sphenoid sinus. *(continued)*

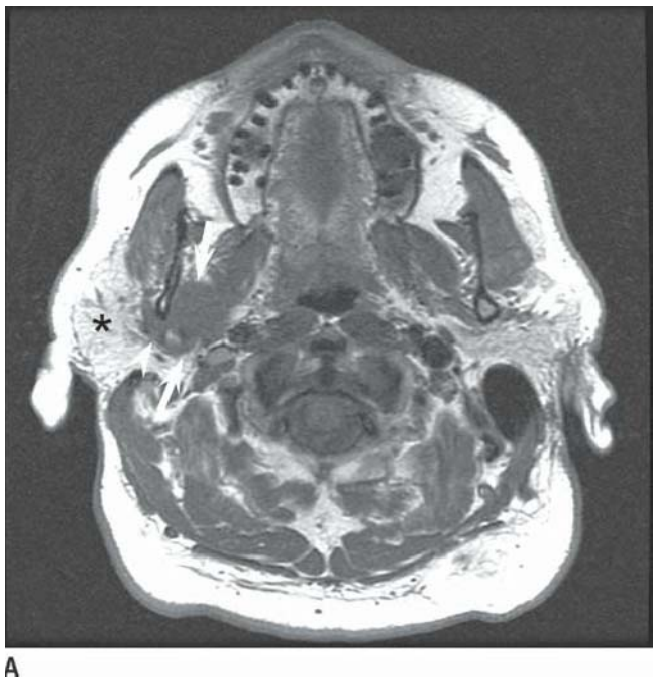
Figure 11.16 *(Continued)* **E:** Perineural spread of tumor extends intracranially along V2 into the left cavernous sinus and Meckel's cave (*arrows*). There is also involvement of the enlarged enhancing left greater superficial petrosal nerve extending to the geniculate ganglion of the left facial nerve (*arrowheads*). Tumor is also seen in the left orbital apex (*asterisk*).

the relationship of the brachial plexus to the adjacent subclavian vessels and clavicle (Fig. 11.20). While unilateral high-resolution imaging in at least two or three planes is preferred, bilateral coronal STIR or axial T1 postcontrast fat suppressed images may be helpful to compare with the unaffected side, particularly if the reader is inexperienced (38).

ULTRASOUND

Imaging Principles

Ultrasound employs a pulse echo technique to generate images. The transducer applied to the patient's skin generates a high-frequency sound wave that is partially transmitted and partially reflected at each interface where there is a difference of acoustic impedance. The same transducer detects the reflected sound energy (echo) from these interfaces, with the depth of each echo estimated by assuming an average speed of sound and using the time of flight. The data are displayed as 2D or 3D gray scale images of the tissues. Using the Doppler frequency shift generated by moving red blood cells, Doppler ultrasound can image the vasculature in the neck (color Doppler sonography) or display the velocities and direction of flow in a vessel (spectral Doppler sonography).



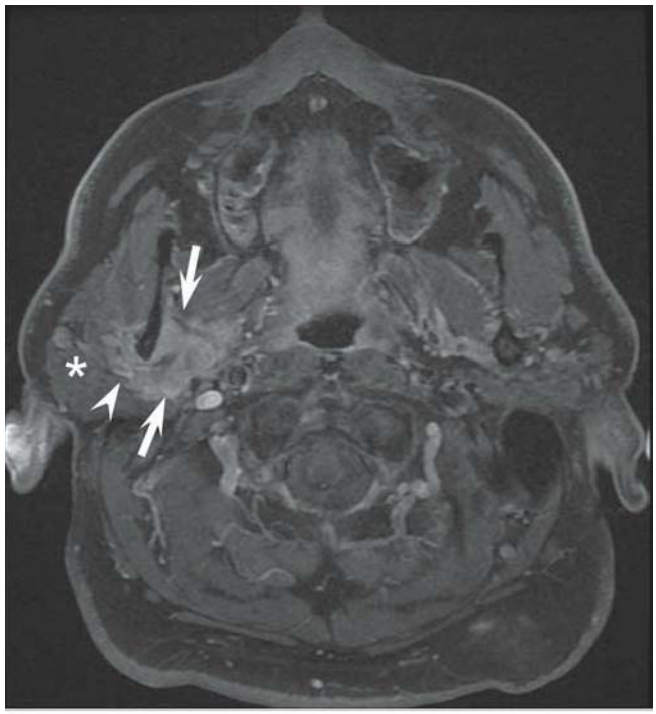


Figure 11.17 Adenoid cystic carcinoma right parotid gland. **A:** Axial T1-weighted image nicely demonstrates an infiltrative T1 intermediate mass (*arrows*) involving the deep portion of the right parotid gland and perineural spread of tumor extending around the ramus of the mandible along the course of the thickened right auriculotemporal nerve (*arrowhead*). The mass is easily distinguished from the surrounding hyperintense fatty parotid parenchyma (*asterisk*). **B:** Axial T2 fat suppressed image. The mass has T2 intermediated signal characteristics (*arrows*), suggesting a malignant neoplasm. There is poor tissue contrast between the mass and the dark fat signal (*asterisk*) in the surrounding parotid parenchyma on this fat suppressed sequence, making it difficult to delineate the margins of the mass. (*continued*)

C

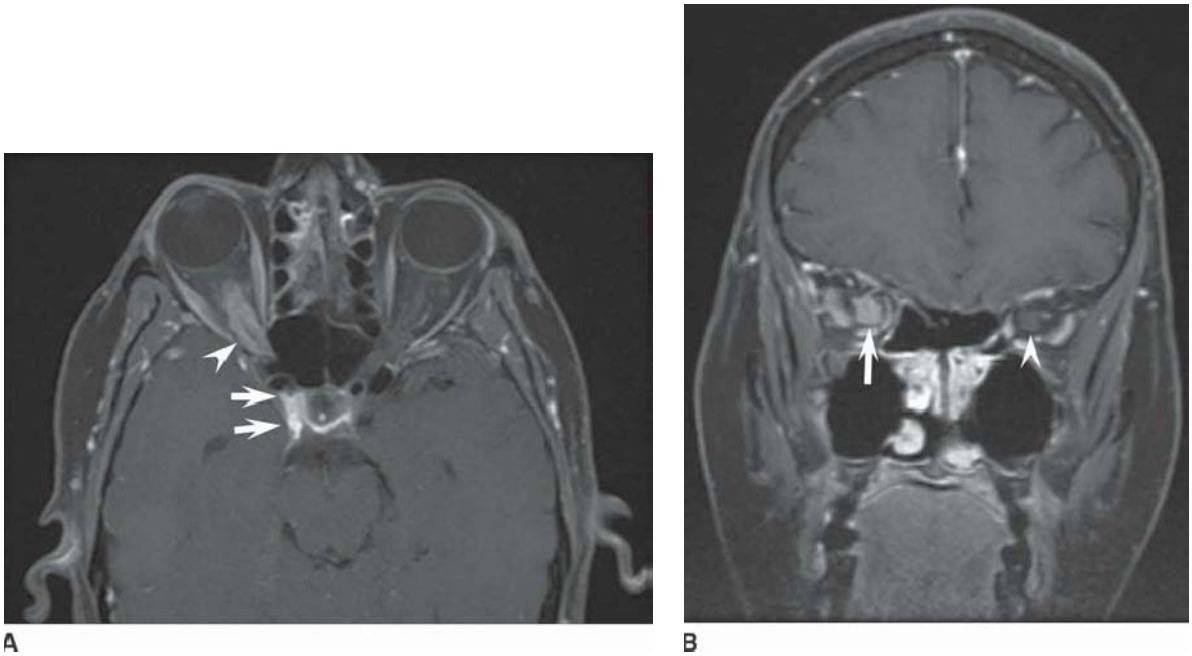

Figure 11.17 *(Continued)* **C:** Axial contrast-enhanced fat suppressed image nicely demonstrates central solid enhancement in the mass (*arrows*), and perineural spread along the thickened enhancing right auriculotemporal nerve (*arrowhead*), easy to see because the fat signal in the surrounding parotid parenchyma (*asterisk*) is dark due to the fat suppression technique.

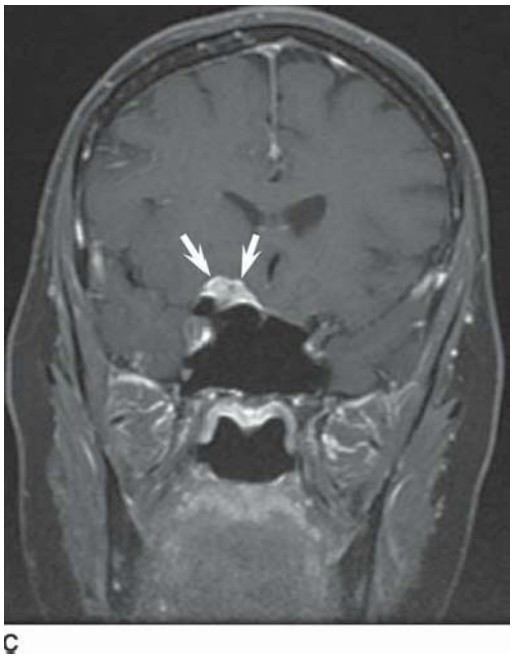
Advantages of ultrasound include its lack of ionizing radiation, relatively low cost, portability, and real time and multiplanar imaging capabilities. At the energies used for medical imaging, there are no known harmful effects. Disadvantages include operator dependence, small field of view in some instances, and difficulty in mastering the anatomy as presented in nonstandard planes.

Indications and Technique



Ultrasound is well suited to evaluate superficial structures in the head and neck, including palpable lymph nodes, parotid masses, thyroid lesions, and parathyroid disease. Ultrasound provides the highest resolution for evaluating focal and diffuse thyroid pathology. Detection of intrathoracic and retrotracheal extension of the thyroid as well as invasion of the esophagus and trachea by thyroid neoplasm is not well imaged with ultrasound and better demonstrated with CT (39). In the management of patients with thyroid cancer, ultrasound is the most sensitive imaging modality to detect nodal metastasis (40).

The portability, low cost, and real-time imaging capabilities of ultrasound are particularly advantageous to perform convenient image guided biopsy of superficial head and neck masses (Fig. 11.21). Ultrasound allows for precise needle tip placement with real-time adjustment of the needle biopsy path during the procedure to avoid critical neurovascular structures. Doppler ultrasound assesses vessel

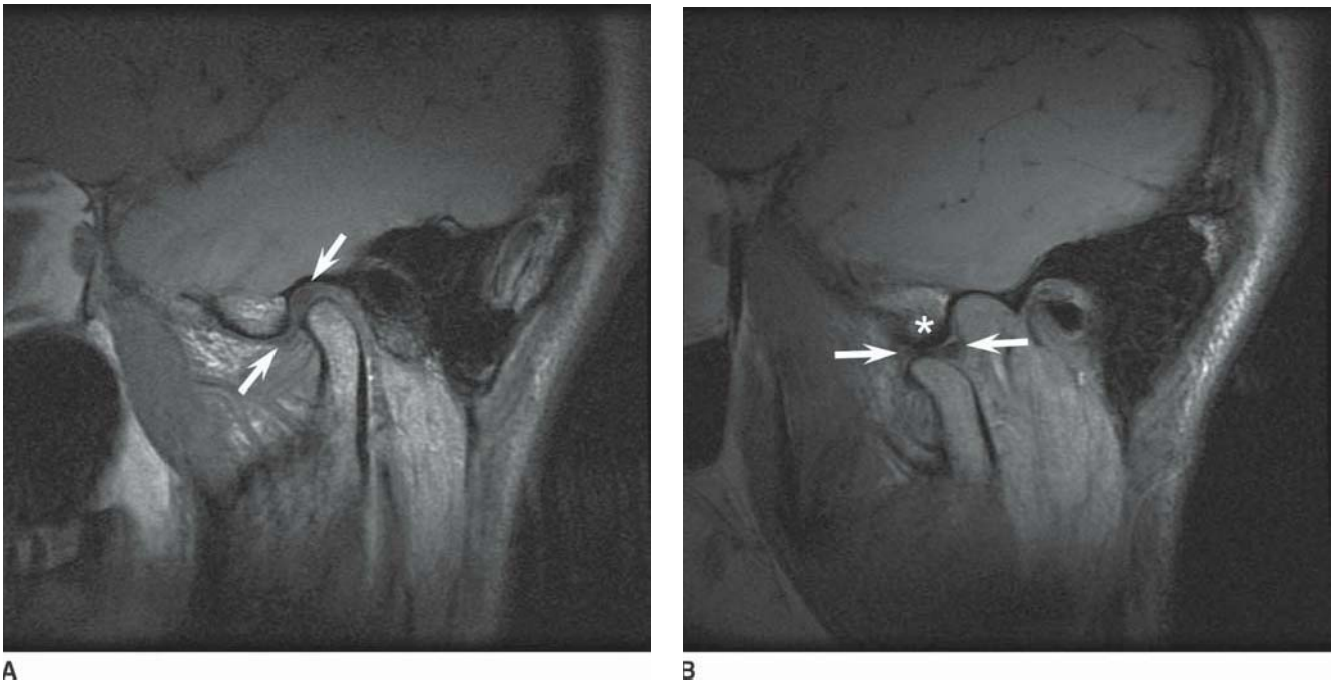
A B

Figure 11.18 Right paraclinoid and optic nerve sheath meningioma. **A:** Contrast-enhanced axial T1-weighted image with fat suppression through the orbits reveals tram-track enhancement of the right optic nerve sheath complex (*arrowhead*) characteristic of meningioma. The abnormal enhancement is well demonstrated because of fat saturation technique applied to the orbital fat. The portion of the mass extending intracranially along the right aspect of the sella (*arrows*) is difficult to see in the axial plane. **B** and **C**: Contrast-enhanced coronal T1-weighted image with fat suppression. The relationship of the enlarged enhancing right optic nerve sheath complex (*arrow*) to the extraocular muscles is seen on the coronal sequence. The left optic nerve sheath complex (*arrowhead*) is normal in appearance. *(continued)*

C

Figure 11.18 *(Continued)* **C:** The right paraclinoid portion of the mass (*arrows*) extending along the posterior planum sphenoidale is better imaged in the coronal plane.

patency and serves as a good screening tool for carotid artery stenosis. Ultrasound is the first study of choice for evaluation of a neck mass in the pediatric population because of its lack of harmful effects and because it does not require preparation, sedation, or contrast administration. Portability and lack of ionizing radiation allow caregivers to be present with the child during imaging which may improve patient cooperation, decrease patient anxiety, and facilitate evaluation of abnormalities. In cases where malignancy is suspected or the lesion is too large to be adequately imaged, MRI or CT can be performed. Ultrasound is more widely utilized in Europe than in the United States, probably because of its operator dependency and cost.



NUCLEAR MEDICINE

Nuclear radiology has both diagnostic and therapeutic applications. While its spatial resolution is poor, it provides functional and physiological information not provided by conventional CT, MRI, and ultrasound. In the head and neck, main applications include positron emission tomography (PET)/CT, thyroid and parathyroid scintigraphy, and to a lesser extent other tumor scintigraphic imaging.

POSITRON EMISSION TOMOGRAPHY

Imaging Principles

PET is a functional imaging technique that employs the use of a radiotracer to illustrate tissue metabolic activity. PET is now frequently performed as a hybrid technique, PET/CT, where PET images are fused with CT images to provide both functional and anatomical information. The

A B

Figure 11.19 Normal TMJ articular disk. **A** and **B**: Sagittal oblique T1-weighted images. **A:** In the closed mouth view, the normal biconcave shaped T1 intermediate disc (*arrows*) is seen between the mandibular condyle and the glenoid fossa. **B:** In the open mouth view, the condyle moves anterior and inferior, beneath the articular eminence (*asterisk*) of the temporal bone. The disc (*arrows*) maintains its normal shape and position interposed between the mandibular condyle and the temporal bone.

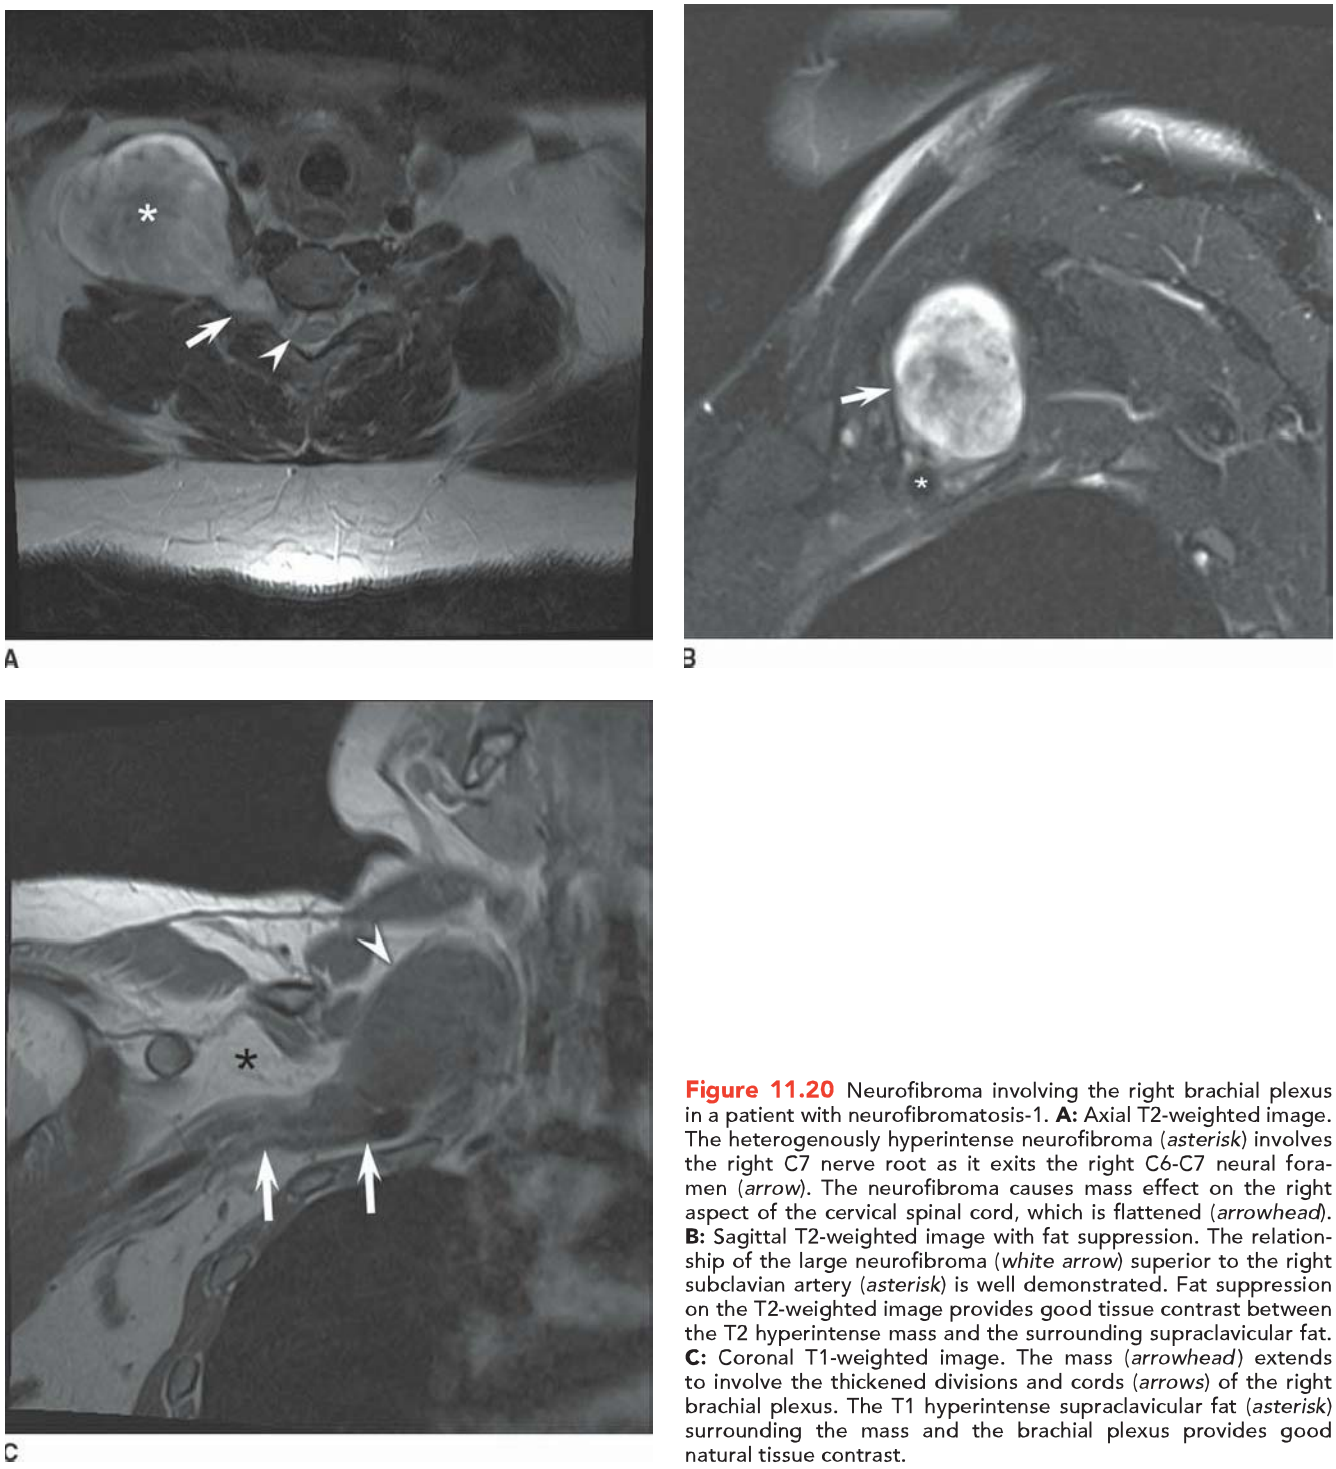


Figure 11.20 Neurofibroma involving the right brachial plexus in a patient with neurofibromatosis-1. **A:** Axial T2-weighted image. The heterogenously hyperintense neurofibroma (*asterisk*) involves the right C7 nerve root as it exits the right C6-C7 neural foramen (*arrow*). The neurofibroma causes mass effect on the right aspect of the cervical spinal cord, which is flattened (*arrowhead*). **B:** Sagittal T2-weighted image with fat suppression. The relationship of the large neurofibroma (*white arrow*) superior to the right subclavian artery (*asterisk*) is well demonstrated. Fat suppression on the T2-weighted image provides good tissue contrast between the T2 hyperintense mass and the surrounding supraclavicular fat. **C:** Coronal T1-weighted image. The mass (*arrowhead*) extends to involve the thickened divisions and cords (*arrows*) of the right brachial plexus. The T1 hyperintense supraclavicular fat (*asterisk*) surrounding the mass and the brachial plexus provides good natural tissue contrast.

most commonly used radiotracer in clinical practice is 18F-labeled fluorodeoxyglucose (FDG), a glucose analog that is actively transported into cells by glucose transport proteins. Once inside the cell, hexokinase phosphorylates the 18F-FDG, forming 18F-FDG-phosphate, which is trapped intracellularly. Many tumor cells have increased numbers of glucose transporters, higher concentrations of hexokinase and higher metabolic rates, all contributing to the preferential uptake of 18F-FDG in neoplastic cells as compared to normal cells. The PET scanner detects the radiation emitted from the 18F-FDG uptake in the patient. After the data are processed by a computer, the tracer distribution throughout the body is displayed coregistered with the CT for anatomic localization.

Modern PET/CT scanners consist of a full ring of coincident PET detectors combined with the CT system, allowing the patient to remain on the same scan table and in the same position to optimize image fusion. This system

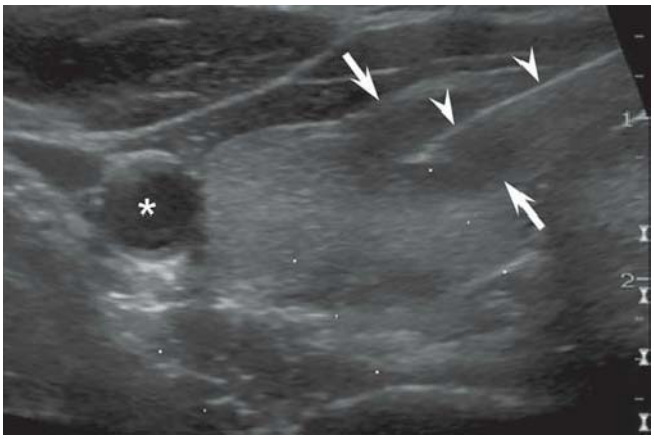

Figure 11.21 Ultrasound guided fine needle aspiration (FNA) of a right thyroid lobe nodule. A hypoechoic nodule (*arrows*) is present in the anteromedial right lobe of the thyroid gland. The linear hyperechoic needle path (*arrowheads*) that extends into the nodule during FNA is clearly seen. The right ICA is just lateral to the gland (*asterisk*). This was nodular hyperplastic goiter.

allows for a quality diagnostic contrast-enhanced neck CT to be obtained simultaneously with the PET and facilitates a comprehensive evaluation of the patient's disease. The PET portion is useful to evaluate nodal status and distant metastasis. The contrast-enhanced neck CT delineates the extent of the primary tumor and its relationship to critical structures and delineates areas of necrotic or cystic tumor that may not be FDG avid.

Disadvantages of PET include poor sensitivity for lesions less than 5- to 10-mm, low spatial resolution and suboptimal specificity. Increased 18F-FDG uptake is not specific to neoplastic cells and occurs in cells with elevated glycolytic activity and metabolism, including at sites of inflammation, infection, tissue repair, and hyperactivity (e.g., muscular).

Applications of PET

Most current applications of FDG-PET are performed using combined PET/CT because it is more accurate than FDG-PET alone, improves reader confidence, and can be used to plan biopsies and adjuvant therapy (41–43). In patients with advanced head and neck squamous cell carcinoma (HNSCC), staging FDG-PET and PET/CT are more sensitive for detecting regional or distant metastatic disease as well as synchronous neoplasms that may be occult by clinical exam or conventional imaging (44,45). When conventional evaluation fails in patients with metastatic carcinoma of the neck and an unknown primary, FDG-PET and PET/CT are useful adjuncts used to direct endoscopic biopsy or identify primary lesions outside the head and neck (Fig. 11.22). A negative PET/CT, however, does not preclude further evaluation with panendoscopy, tonsillectomy, and blind biopsies as the resolution of PET/CT is limited to approximately 5–10 mm and small or superficial lesions may be below the resolution of the study (44,45). Similarly, the spatial resolution limits the detection for microscopic metastasis and currently FDG-PET and PET/CT are not considered accurate enough to guide therapy in the clinically defined N0 neck.

In patients with HNSCC treated with nonsurgical organ preservation therapy (NSOPT) such as chemoradiation, PET/CT is more accurate than conventional imaging in detecting recurrent or residual neoplasm and is useful to monitor treatment response to therapy. Following chemoradiotherapy, the high negative predictive value of FDG-PET and PET/CT is useful to exclude locoregional disease and distant metastases (46–50) (Fig. 11.23). Some authors have suggested that a negative PET/CT may obviate the need for planned neck dissection (44,50,51). Furthermore, a negative PET/CT following NSOPT has prognostic value and has been associated with greater

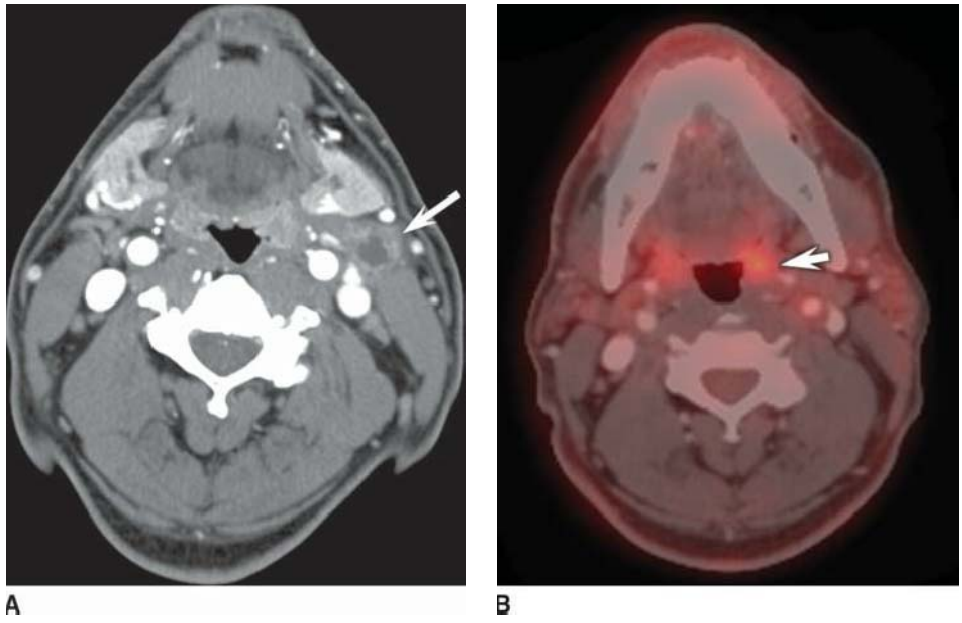

Figure 11.22 Left faucial tonsil carcinoma with metastatic left level II node. A 62-year-old male presented with complaint of palpable left neck mass. **A:** Axial contrast-enhanced neck CT. A malignant appearing necrotic left level II lymph node (*arrow*) is seen. No primary mucosal neoplasm was seen on the CT or clinical exam. FNA of the lymph node was consistent with squamous cell carcinoma. **B:** Fused F18-FDG PET/CT. Asymmetric FDG uptake in the left faucial tonsil (*arrow*) was suspicious for a primary left faucial tonsil carcinoma. Directed biopsy of the left faucial tonsil was positive for squamous cell carcinoma, confirming it as the source of the left level II lymph node metastasis.

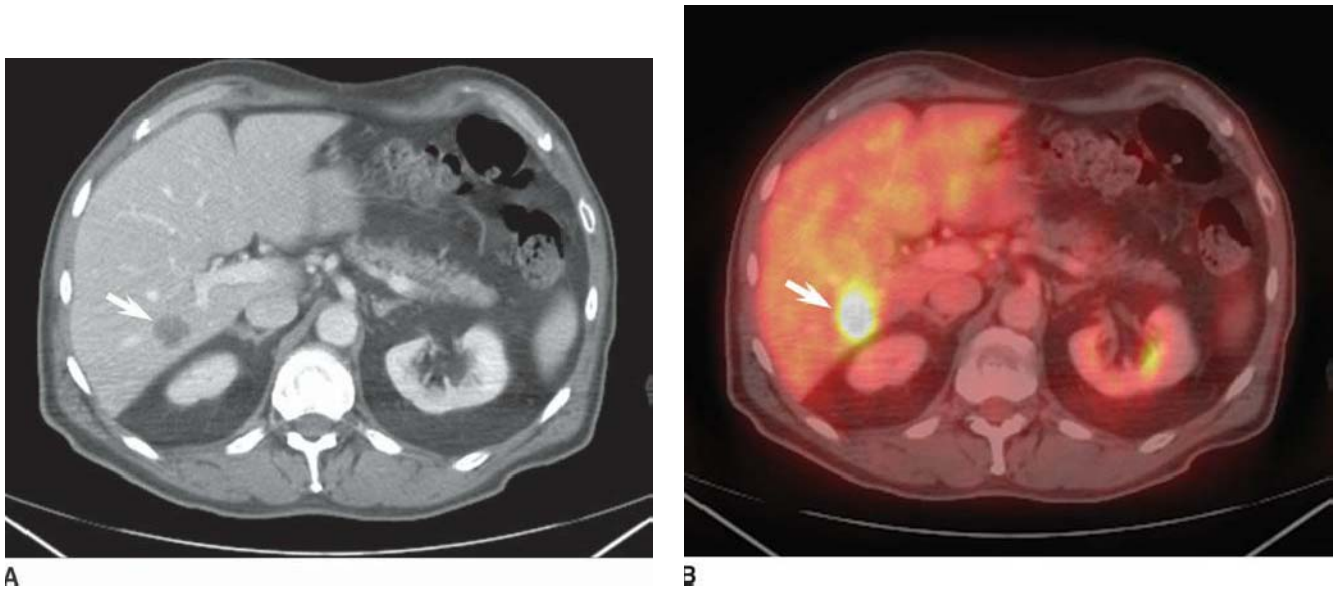

Figure 11.23 Isolated squamous cell carcinoma metastasis to the liver 6 months following completion of chemoradiotherapy for a T2N2b supraglottic squamous cell carcinoma. **A:** Contrast-enhanced CT from diagnostic whole body PET/CT study. A hypoattenuating mass (*arrow*) is seen in the posterior segment of the right lobe of the liver. **B:** Fused F18-FDG PET/CT image demonstrates intense F18-FDG avidity (*arrow*) in the mass suspicious for malignant neoplasm. This was biopsy proven isolated metastatic squamous cell carcinoma. The patient underwent partial hepatectomy.

2-year progression-free survival and overall survival rates (46,47,49).

FDG-PET and PET/CT have applications in the management of other head and neck malignancies as well. In patients with lymphoma and melanoma, PET/CT is useful for initial staging of disease, assessing response to treatment, and surveying for disease recurrence. Following treatment for differentiated thyroid carcinoma, FDG-PET and PET/CT are useful for the detection of recurrent or metastatic disease in patients with elevated serum thyroglobulin and a negative whole body radioiodine scan, with sensitivities ranging from 70% to 95%. PET/CT is more accurate for precise localization of recurrent tumor when compared with PET alone and may alter management (44,52). Following surgery for medullary thyroid carcinoma, FDG-PET may be helpful in the detection of recurrent or residual disease in patients with elevated calcitonin levels. However, reported sensitivities are variable and the absence of FDG uptake does not exclude disease (44,52,53). There has been research on other more specific PET radiotracers and early data suggest that 18 F-FDOPA PET has greater sensitivity than FDG-PET for detection of recurrent medullary thyroid carcinoma in this population (52).

SCINTIGRAPHY

Nuclear Scintigraphy

Imaging Principles with Single Photon Emitters

Aside from PET, most nuclear scintigraphy is performed with a standard gamma camera and radiopharmaceuticals containing isotopes emitting single gamma photons. Patients are administered a radionuclide which then distributes and accumulates in the body. The choice of radiopharmaceutical administered is determined by the clinical question, the normal biodistribution of the radiotracer and influenced by practical issues such as cost, half-life, image quality and radiation absorbed dose.

Thyroid Scintigraphy

Using the sodium/iodine symporter, the follicular cells of the thyroid gland concentrate iodide, which is then oxidized and organified into the protein thyroglobulin. Thyroglobulin is then used to produce the thyroid hormones triiodothyronine (T3) and thyroxine (T4). Because iodine is essential to thyroid physiology, iodine and its analogues are well suited to thyroid scintigraphy. The radionuclides used for thyroid imaging are listed in Table 11.1.

In otolaryngology, the main application of thyroid scintigraphy is in the management of patients with differentiated thyroid cancer. Following total thyroidectomy or near total thyroidectomy for thyroid cancer, radioactive iodine imaging is employed to identify thyroid remnant tissue, residual tumor, and metastasis amenable to I-131 treatment (Fig. 11.24). After definitive treatment for differentiated thyroid cancer, radioiodine whole-body imaging may be used to survey for local disease recurrence or distant metastasis (54).

In benign thyroid disease, diagnostic thyroid scintigraphy is most commonly used to evaluate causes of hyperthyroidism, though additional applications include

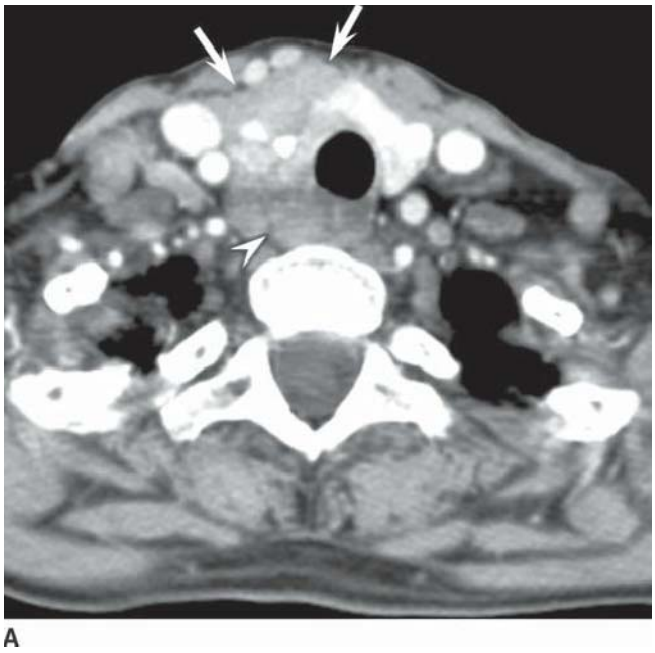

TABLE 11.1 RADIONUCLIDES USED FOR THYROID SCINTIGRAPHY

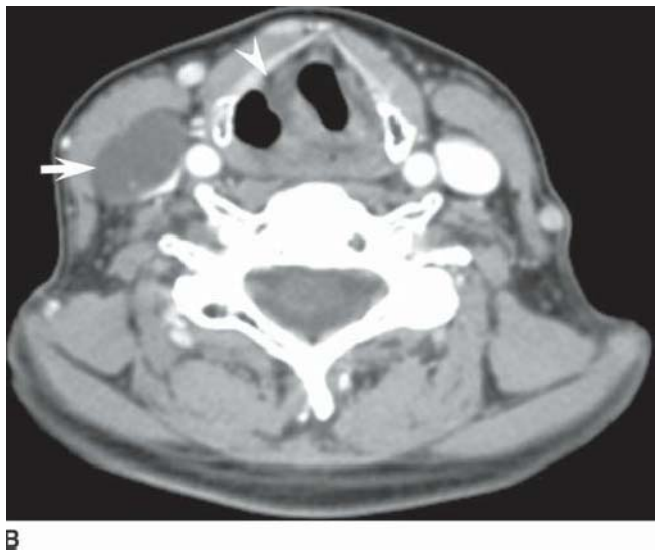
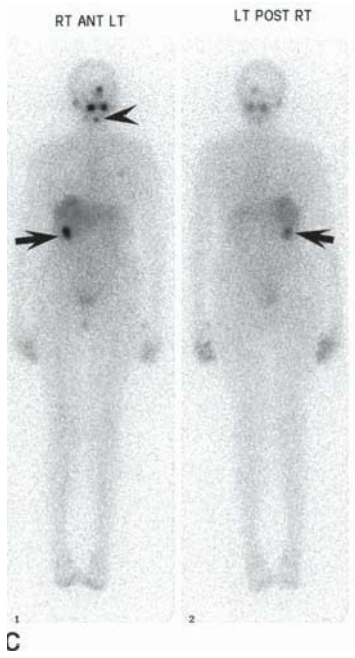
Radionuclide	Half-life	Principal Photon (keV)
I-123	13 h	159
I-131	8 d	364
^{99m}Tc	6 h	140



assessment of function in thyroid nodules and diagnostic work up of congenital hypothyroidism. Therapeutically, I-131 can also be used to treat Graves disease and toxic nodular disease.

Parathyroid Scintigraphy



Hyperparathyroidism due to parathyroid adenoma is the most common type of parathyroid disease. Preoperative localization of parathyroid disease is crucial because of the increasing popularity of minimally invasive parathyroid surgery focused on limited dissection of the abnormal parathyroid gland (55,56). There are several parathyroid localizing radiotracers available, including technetium-^{99m}Tc sestamibi, technetium, ^{99m}Tc tetrofosmin, and thallous chloride Tl-201. Initially, Tl-201-chloride-^{99m}Tc pertechnetate subtraction imaging was the most widely accepted parathyroid scintigraphy, but it has been replaced with technetium ^{99m}Tc sestamibi, the current most commonly used radiotracer for parathyroid imaging.

A

B

C

Figure 11.24 Metastatic papillary thyroid carcinoma. **A,B:** Axial contrast-enhanced neck CT. **A:** A hypoattenuating partially calcified mass (*arrows*) is seen in the right lobe of the thyroid extending into the right tracheoesophageal groove (*arrowhead*). **B:** The right aryepiglottic fold (*arrowhead*) is medialized due to the right vocal cord paralysis and there is a cystic metastatic cystic right level III cervical lymph node (*arrow*), indicating the thyroid mass is malignant. **C:** Whole body I-131 scintigraphy following thyroidectomy and I-131 treatment of metastasis. There is focal increased uptake (*arrow*) in the right lobe of the liver and in the submental region (*arrowhead*) due to metastatic papillary thyroid carcinoma. Physiologic tracer uptake is seen in the salivary glands, nasopharynx, liver, bowel, and bladder.

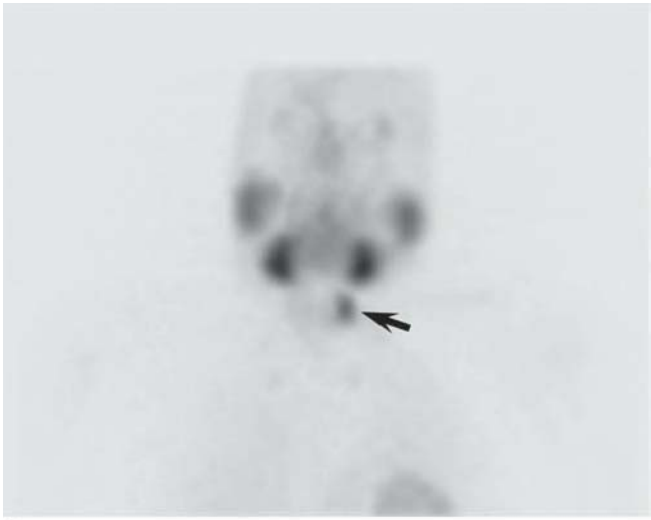
Dual-phase imaging is preferred due to greater sensitivity (57). A typical protocol includes images obtained at 15 minutes and 2 to 3 hours after radiotracer administration. Sestamibi is taken up more avidly and usually retained longer by parathyroid adenoma and hyperplastic parathyroid tissue as compared to normal parathyroid and thyroid tissue. Parathyroid adenoma is characterized by delayed clearance of tracer. Images should extend from the base of the jaw to the apex of the heart to include potential ectopic sites in the neck and mediastinum. At some institutions, subtraction techniques are employed in which a second radiotracer taken up by the thyroid gland (such as ^{123}I or ^{99m}Tc pertechnetate) is administered simultaneously with ^{99m}Tc sestamibi. Subtraction images are produced to increase conspicuity of the parathyroid tissue, but have not been clearly shown to be superior to routine dual-phase imaging without subtraction technique (58). Two-dimensional planar versus three-dimensional single-photon emission computed tomography (SPECT) imaging techniques can be employed. The reported sensitivity of ^{99m}Tc-sestamibi parathyroid scintigraphy for the detection of solitary parathyroid adenoma ranges from 68% to 95% (56,59). False negatives are more common with multigland disease and parathyroid hyperplasia.

3-D single-photon emission computed tomography (SPECT 3-D) increases the sensitivity of parathyroid scintigraphy and improves resolution and anatomic localization by helping differentiate parathyroid activity from overlying thyroid tissue (60–62). More recently, the utility of coregistered ^{99m}Tc-sestamibi SPECT with CT (SPECT/CT) has been investigated. Initial results suggest SPECT/CT offers the advantage of improved anatomic localization particularly in the case of ectopic mediastinal parathyroid adenoma and may improve reader confidence and sensitivity, though further research is required to establish the appropriate use of this combined modality (Fig. 11.25) (56).

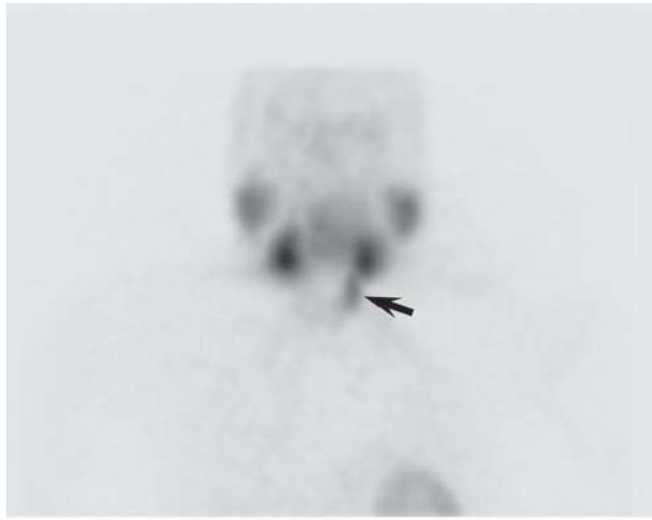
The functional information of parathyroid scintigraphy combined with the anatomic information of sonography offers the best sensitivity and accuracy for localization of solitary parathyroid adenoma (56,63). However, the sensitivity of each technique and the sensitivity of combining results of parathyroid scintigraphy and ultrasound remain suboptimal for the detection of multiglandular disease and parathyroid hyperplasia (56,64). MRI and CT are typically used as adjunctive imaging in difficult cases or cases of suspected ectopic parathyroid glands. Four-dimensional CT (4-D-CT) is a promising technique that relies on characteristic early enhancement of hyperfunctioning parathyroid tissue to localize parathyroid disease (65,66). It is a dynamic contrast-enhanced (DCE) CT that requires multiple acquisitions of CT data at several time points through the potential locations of normal and ectopic parathyroid tissue, increasing radiation dose from the study. It is typically reserved for cases with prior unsuccessful surgery or indeterminate ultrasound and parathyroid scintigraphy. Whether it offers a distinct reproducible advantage over a high-resolution single-phase contrast-enhanced CT is not yet established (67).

Somatostatin Scintigraphy

Somatostatin receptor scintigraphy (SRS) can be useful in the management of patients with neuroendocrine tumors in the head and neck, which overexpress somatostatin receptors and most notably include paragangliomas and medullary thyroid carcinoma. Paragangliomas or glomus tumors in the head and neck typically arise from parasympathetic paraganglia and are usually nonfunctioning. They can be sporadic or familial and multiplicity can occur with both, but is more common in familial paragangliomas (68). SRS using the radiolabeled somatostatin analogue 111In-DTPA-octreotide has been shown to be sensitive for the detection of paraganglia and may be useful when cross-sectional imaging is inconclusive, when staging is required, and in screening of familial cases (68,69).



SRS may be helpful in localizing recurrent disease in postoperative patients with a history of medullary thyroid carcinoma and a high serum calcitonin level. Localization of tumor using 111In-DTPA-octreotide SPECT/CT is based on tumor expression of somatostatin receptors. The reported sensitivity of 111In-DTPA-octreotide scintigraphy for the detection of recurrent or residual disease is highly variable and the optimal imaging modality for detecting recurrent or residual disease is controversial (52).



Other Miscellaneous Scintigraphic Applications

^{99m}Tc pertechnetate is taken up by the salivary glands and excreted into saliva. Both Warthin tumor and oncocytoma demonstrate increased ^{99m}Tc pertechnetate uptake due to the presence of mitochondrium-rich oncocytes. Pertechnetate scintigraphy can be useful to support a diagnosis of Warthin tumor if observation is being considered in a patient with a parotid mass (30).

SIALOGRAPHY

Conventional sialography is infrequently performed due to advances in cross-sectional imaging and the clinical management of nonneoplastic salivary gland disease, including improved autoimmune serologic testing and the development of sialoendoscopy. It employs the use of iodinated contrast to demonstrate the intraglandular and extraglandular anatomy of the parotid or submandibular gland ductal system. The opening of the Stensen or Wharton duct is located and dilated using a lacrimal probe, after which a small canula is inserted into the duct and a small amount of dense water-soluble iodinated contrast is gently hand injected. Plain radiographs in the anteroposterior (AP) and lateral projections are then obtained and repeated after a secretogogue is administered to ensure emptying of the gland. Conventional sialography is contraindicated in patients with acute sialoadenitis. Disadvantages include the invasiveness of the procedure,

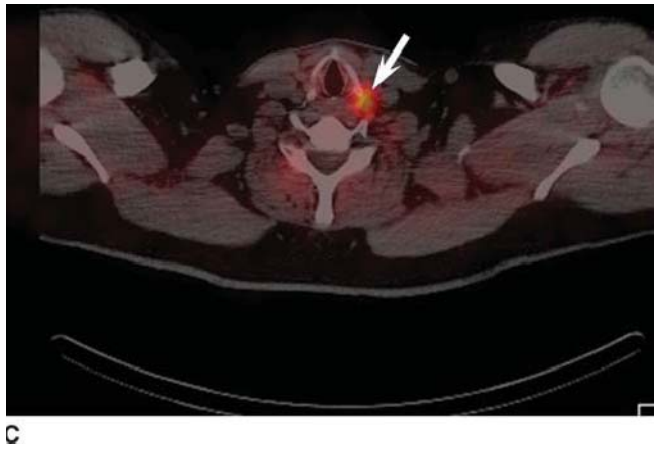


Figure 11.25 Ectopic parathyroid adenoma. A 42-year-old male with MEN-1 status post total thyroidectomy and parathyroid adenoma resection with persistent hypercalcemia. **A** and **B**: Planar SPECT images after ^{99m}Tc sestamibi injection at 20 minutes **(A)** and 2 hours **(B)**. **A:** At 20 minutes postinjection, there is a focus of increased tracer uptake (*arrow*) seen in the left neck **B:** It (*arrow*) persists on 2 hour delayed images and is consistent with parathyroid adenoma. Normal physiologic tracer uptake is seen in the salivary glands and heart. **C:** Fused axial SPECT/CT fused images localize the persistent radiotracer uptake (*arrow*) due to the ectopic parathyroid adenoma to the left tracheoesophageal groove.

use of ionizing radiation, risk of duct trauma, and potential risk of contrast reaction.

In the past, indications for sialography included detection of small sialoliths, evaluation of the extent of ductal damage as a sequela of infection, and differentiation of chronic sialoadenitis, Sjogren syndrome, and sialosis. Currently, conventional sialography is reserved for patients in which the clinical evaluation, autoimmune serology and CT, MRI, or ultrasound cannot identify the cause of the patient's symptoms and ductal disease is suspected (30). It may be helpful in evaluation of patients with mixed connective tissue disease, an overlap autoimmune disorder with clinical features commonly seen with systemic lupus erythematosus, scleroderma, and polymyositis. Sialography remains the only study to demonstrate the fine anatomy of the salivary ductal system (70). It is sensitive for the detection of ductal stricture and sialolithiasis, which can be seen as calcifications on plain films and filling defects during sialography. In the case of autoimmune disease, pruning of the intraglandular ducts and numerous areas of globular and spherical collections of contrast are seen throughout the gland that remain following administration of a secretogogue (Fig. 11.26). The central larger ductal system is sometimes spared (71).

MRI sialography is an emerging noninvasive way of imaging the parotid ducts that relies on the use of saliva within the ductal system as a natural contrast agent. Various protocols using heavily T2-weighted sequences typically with fat suppression are utilized. Advantages of MRI sialography include the noninvasive imaging technique as well as the ability to directly image the surrounding parenchyma and soft tissues with standard salivary gland MRI. In some cases, a sialogogue is administered prior to imaging to improve duct visualization. Typically, the fluid filled main duct, primary and secondary branches are well depicted but the tertiary branches that are seen with conventional sialography are not well delineated with MRI sialography (72,73). It performs well in detecting strictures; however, currently, suboptimal spacial resolution limits the sensitivity for detection of small sialoliths or early sialectasis (72–74). In one study, MRI sialography was reported to be accurate in the staging of Sjogren disease when correlated with conventional sialography, though some authors report discordant sialoectatic patterns when comparing

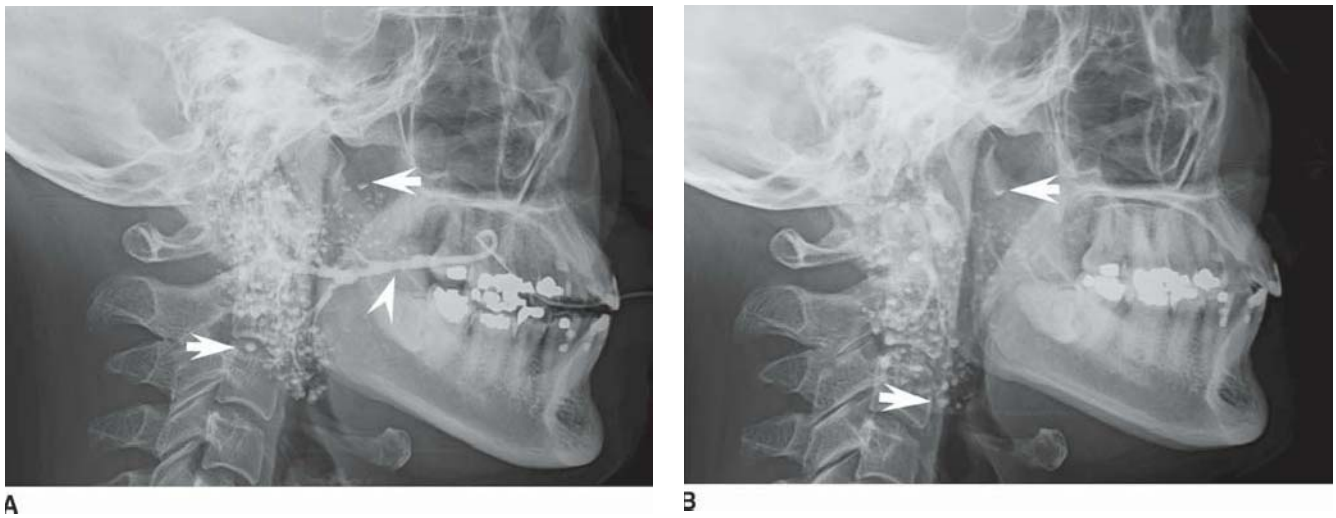

Figure 11.26 Sjogren syndrome. **A:** Conventional sialogram. There is marked irregularity of the intraglandular and extraglandular (*arrowhead*) ductal system with innumerable globular areas of acinar contrast pooling (*arrows*). **B:** Following administration of a sialogogue, there is retention of contrast within the intraglandular ducts and acinar pools (*arrows*). The Stensen duct empties.

MRI sialography and conventional sialography in later stages of disease (75,76). Further research to optimize and validate MRI sialography in a nonselected patient population is required before it becomes a routine part of salivary gland imaging protocols.

FLUOROSCOPY

Fluoroscopy is an imaging technique that employs the use of x-rays to provide real-time images of dynamic processes and procedures on a video monitor. The most commonly performed fluoroscopic studies in head and neck imaging are the modified barium swallow and the esophagram, which are complimentary to endoscopic evaluation and helpful in evaluating the anatomy, motility, and mucosa of the aerodigestive tract.

Modified Barium Swallow (Video Fluoroscopic Evaluation of Swallowing)

Oropharyngeal dysphagia frequently results as a disorder of the swallowing process. Dynamic swallowing is best evaluated with a modified barium swallow study, a real-time high definition videofluoroscopic exam of the oral and pharyngeal phases of swallowing. The study is ideally performed by a radiologist in conjunction with a speech pathologist trained in dysphagia management. A modified barium swallow study is indicated in patients with signs of pharyngeal dysphagia, including coughing and choking while eating or drinking and globus sensation. During a modified barium swallow, the mucosal space is imaged from the lips to the posterior pharyngeal wall and from the nasopharynx to the upper cervical esophagus. It focuses on the oral cavity, oropharynx, nasopharynx, hypopharynx, larynx, and cervical esophagus. Patients are administered controlled and uncontrolled volumes of various barium coated consistencies and imaged while seated upright, mainly in the lateral projection. The study is tailored to the patient's complaints, history, and risk of aspiration. The goal of the study is to simulate habitual swallowing and evaluate for aspiration and its causes. It differs from an esophagram (barium swallow), which is a fluoroscopic study focused on the hypopharynx and cervical and thoracic esophagus.

Esophagram (Barium Swallow)

An esophagram is a fluoroscopic study focused on evaluation of the motility, mucosa, and anatomy of the hypopharynx, cervical, and thoracic esophagus. A patient is administered barium and full column contrast images of the esophagus are obtained. Double-contrast imaging performed in the upright position evaluates for mucosal lesions in addition to assessing motility and contour abnormalities. Single-contrast imaging is performed in the prone position evaluating for stricture, contour abnormality, and motility. A 13-mm pill can be administered to evaluate for stricture at the gastroesophageal junction. Provocative maneuvers can be performed to assess for reflux. Common indications include evaluation for motility disorder, reflux, hiatal hernia, stricture, diverticulum, leak following surgery and symptoms of dysphagia (Fig. 11.27).

RADIOGRAPHY

With advances in cross-sectional imaging, plain film radiography has a limited role in head and neck imaging. Computed radiography and digital radiography have largely replaced screen-film techniques. Images are captured

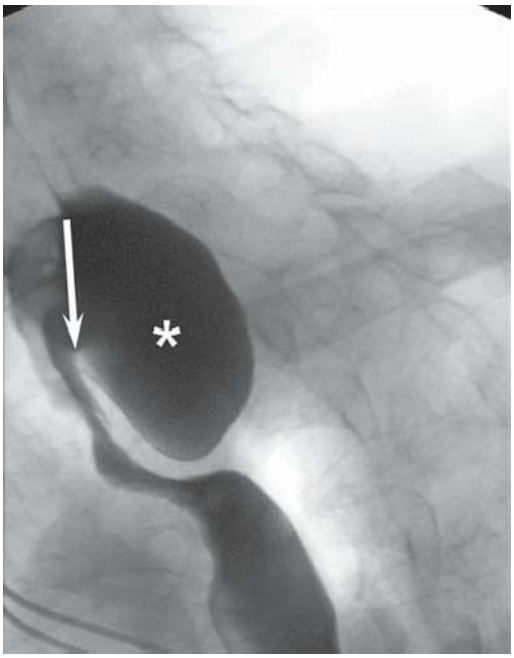

Figure 11.27 Zenker diverticulum. Oblique view from a single-contrast esophagram (barium swallow). There is a large Zenker diverticulum (*asterisk*) that originates posteriorly from the hypopharynx just above the cricopharyngeus muscle (*arrow*) and extends posteriorly to the lower cervical esophagus.

on reusable digital detectors and transferred to a computer for viewing. Advantages of digital imaging include the ability to postprocess the images, increased patient throughput, and widespread availability of images.

AP and lateral soft tissue plain films of the neck are still employed in pediatric imaging and may be particularly helpful to evaluate the airway in pediatric patients with signs of respiratory distress or to evaluate for radiodense foreign body. CT has replaced radiography as the preferred imaging modality for evaluation of the paranasal sinuses and temporal bones.

ADVANCED IMAGING TECHNIQUES

The conventional cross-sectional imaging modalities of CT, MRI, and ultrasound rely on morphological and soft tissue contrast to detect pathology in the head and neck. Unfortunately, conventional anatomic imaging lacks sensitivity for microscopic disease or early lesion detectability in cases of neoplasm. This is particularly problematic in the treated head and neck where treatment changes cause soft tissue distortion and can be difficult to distinguish from recurrent disease. Many of the areas of research in head and neck imaging focus on functional oncologic applications including metabolic and molecular imaging with the intention of overcoming the pitfalls of conventional anatomic imaging. Areas of research are vast, but include hypoxia and epidermal growth factor receptor (EGFR) imaging with novel PET radiotracers, CT and MRI perfusion imaging, and novel MRI contrast agents.

Tumor Hypoxia Imaging

Tumor hypoxia has been demonstrated in head and neck squamous cell carcinomas (HNSCCs) and is associated with resistance to the cytotoxic effects of radiotherapy and chemotherapy (77). It is associated with poor local control of tumor, disease-free survival, and overall survival (78). Consequently, PET/CT research has focused on tumor hypoxia imaging using hypoxic radiotracers such as 18F-fluoromisonidazole (18F-FMISO) and 60Cu-ATSM in an attempt to identify tumors at greater risk for resistance to standard chemoradiotherapy that would benefit from tailored alternate chemoradiotherapy or novel therapies such as radiation sensitizers or hypoxic cell cytotoxins (50,77,79–81).

EGFR Imaging

Epidermal growth factor is a protooncogene that promotes tumor progression and is frequently elevated in HNSCCs compared to normal mucosa. It has been associated with reduced survival and poor prognosis in patients with HNSCC (82). EGFR targeted therapy using monoclonal antibodies such as cetuximab when combined with radiation and conventional chemotherapy show promising results, though only in a subset of patients (83,84). As a result, targeted EGFR imaging using several novel PET probes has been the subject of research with the intentions of identifying patients who will respond to anti-EGFR therapy and monitoring clinical response in a specific manner (85–89). The best approach to EGFR imaging is controversial because of a lack of correlation between cetuximab response and total EGFR expression level (90).

Tumor Perfusion Imaging

NSOPT with chemoradiation has increasingly become the treatment of choice for locoregionally advanced head and HNSCC. In patients who fail NSOPT, salvage rates are poor. Attempts at diagnostic stratification of patients who will respond to NSOPT with functional imaging such as CT perfusion and DCE MRI have been sought (91–95). CT perfusion is a dynamic functional modality that noninvasively quantifies microvascular changes of neoplasms including blood volume (BV), blood flow (BF), mean transit time, and permeability surface area product (PS). Increased capillary permeability, BF, and BV in HNSCC as compared with normal tissues have been demonstrated (96). Promising potential applications include primary tumor staging and prediction of disease-free survival, prediction of tumor response to therapy and monitoring conventional cytotoxic therapy. Data suggest that HNSCC with elevated BF and BV are more responsive to NSOPT than tumors with low BF and BV (91,92,97,98). Preliminary data suggest that serial reductions in BV are predictive of response to therapy and BF may be useful to predict progression-free survival

in patients with advanced HNSCC treated with NSOPT (92,93). In addition, baseline elevated BF and PS may have long-term predictive value for local tumor control (99). Due to technical factors and efforts to minimize radiation dose (multiple acquisitions of CT data through the area of interest must be obtained), CT perfusion imaging cannot be applied to the entire volume of the neck and can only be used to image a localized area of interest.

Characterization of tumor perfusion using DCE-MRI with gadopentetate dimeglumine (Gd-DTPA) is also being investigated as a tool to predict treatment response and outcomes in patients treated for HNSCC. Its lack of ionizing radiation is advantageous. DCE-MRI evaluates changes in signal intensity over time related to Gd-DTPA administration and can be used to noninvasively characterize tumor perfusion, tumor-vessel permeability, and extracellular–extravascular volume fraction (100). The parameter K_{trans} (volume transfer constant) can be calculated and is thought to reflect tumor BF and microvascular permeability (101). K_{trans} and BV may predict early response to NSOPT in HNSCC (94,95). Further validation of CT perfusion and DCE-MRI is required before the routine use of these technologies is implemented into clinical practice.

Novel Contrast Agents

The application of superparamagnetic iron oxide nanoparticles as a novel contrast agent to improve sensitivity for detection of metastasis in morphologically normal appearing nodes is the subject of research. The particles are administered intravenously and theoretically accumulate in normal lymph nodes, which on T2*-weighted gradient echo sequences appears as dark or markedly decreased signal. Metastatic nodes usually have foci of T2 hyperintense signal. Initial trials suggest there is improved sensitivity for detection of nodal metastasis compared to conventional contrast agents (102,103).

RADIATION SAFETY AND DOSE

With the advent of helical multidetector CT, the increased utilization of CT imaging has led to a substantial increase in the population's cumulative exposure to ionizing radiation and concerns among the medical community and public regarding the potential adverse effects (104,105). In response to this public health concern, the American College of Radiology appointed a Blue Ribbon Panel on Radiation Dose in Medicine in 2006 that offered recommendations to counteract trends contributing to unnecessary radiation exposure (105). Since then numerous strategies for CT dose reduction have been implemented by the imaging community (105–107). In addition, the Alliance for Radiation Safety in Pediatric Imaging was formed in 2007, which implemented the successful Image Gently™ campaign to increase awareness of radiation risk in children and offer recommendations to minimize radiation dose when imaging this population.

Radiologists and medical physicists adhere to the As Low as Reasonably Achievable (ALARA) principle that advocates minimizing dose while obtaining quality diagnostic imaging. The radiologist is a good resource regarding radiation safety though some basic radiation exposure principles should be understood by clinicians ordering studies. The main risk associated with exposure to ionizing radiation in adults and children is cancer, and while the risk is low with medical imaging, it is not zero. The fetus is particularly sensitive to radiation exposure and potential adverse effects include mental retardation, organ malformations, and childhood cancer. Imaging studies outside of the abdomen result in minimal fetal exposure and, when clinically necessary, can be performed safely with modifications taken to minimize exposure to the fetus. Children are more sensitive to ionizing radiation and radiation-induced cancer mortality risk in children is three to five times higher than for adults due to both increased organ sensitivity and longer life expectancy (108). With increasing age, the risk of a radiation-induced cancer decreases. The most optimal way to reduce radiation dose is to avoid unnecessary exams and use alternate imaging modalities such as ultrasound and MRI when indicated. If ordered appropriately, the benefit of a medically indicated CT scan far exceeds the estimated risk of radiation exposure.

A "SPACE"-BASED APPROACH TO IMAGE INTERPRETATION

The head and neck region is divided by layers of fascia into spaces. The fascia act as barriers to the spread of disease and have been variably described by anatomists and surgeons (109–111). Advances in cross-sectional imaging lead to improved visualization of the deep structures of the head and neck and renewed interest among radiologists to understand the spaces and fascial planes (112–114). A space-based approach to image interpretation has since been popularized among radiologists as a way of simplifying the imaging differential diagnosis of pathology in the deep structures of the head and neck. The center of a lesion as well as patterns of displacement of the adjacent structures, particularly the parapharyngeal fat and carotid sheath, can help to assign a process to a space. Once the process is assigned to a space and knowing the structures that exist within the space, a limited meaningful space-specific differential diagnosis in the context of the patient's age, sex, and clinical presentation can be generated. The following is a brief summary of the spaces used by radiologists to approach pathology in the neck. It is not intended to teach image interpretation, but rather to provide a foundation for understanding the space-based approach to image interpretation. As previously stated, the description and terminology used to describe these spaces is variable and the following terminology presented has been chosen

TABLE 11.2 DIFFERENTIAL DIAGNOSIS OF MORE COMMON PATHOLOGY OCCURRING IN THE HEAD AND NECK BY SPACE[a]

Space	Differential Diagnosis
Pharyngeal mucosal	Infection and sequela of infection (including faucial tonsil abscess), squamous cell carcinoma, lymphoma, minor salivary gland neoplasm, Tornwaldt cyst
Masticator	Odontogenic infection and abscess, osteomyelitis, mesenchymal neoplasms, metastases/myeloma, secondary extension of tumors from adjacent spaces and skull base, perineural spread of neoplasm, nerve sheath tumors, vascular malformations
Parotid	Salivary gland tumors; squamous cell carcinoma; lymphadenopathy; perineural spread of tumor; parotitis; sialolithiasis; benign lymphoepithelial lesions; lipoma, branchial cleft cysts, and nerve sheath tumors
Buccal	Cellulitis/abscess, lymphadenopathy, minor salivary gland neoplasms, secondary involvement by squamous cell carcinoma, vascular malformations, lipoma, sialolithiasis, primary mesenchymal neoplasms
Retropharyngeal	Lymphadenopathy; edema, abscess; hematoma; direct extension of tumor from adjacent structures; extension of discitis/osteomyelitis
Prestyloid parapharyngeal	Deep portion parotid gland tumors, minor salivary gland tumors, extension of processes (typically infectious or neoplastic) from the adjacent spaces, atypical second branchial cleft cyst, lipoma, vascular malformations
Carotid sheath/poststyloid parapharyngeal	Lymphadenopathy, pseudoaneurysm/dissection, secondary extension of tumors and infection from adjacent spaces and skull base, paraganglioma, neuroblastoma, nerve sheath tumors, venous thrombosis
Submandibular	Lymphadenopathy, sialolithiasis, infection/abscess, salivary gland neoplasms, plunging ranula, secondary extension of oral cavity neoplasm, second branchial cleft cyst, thyroglossal duct cyst, vascular malformations, dermoid/epidermoid
Sublingual	Secondary extension of odontogenic infection and squamous cell carcinoma, ranula, sialolithiasis and obstructed submandibular duct, minor salivary gland neoplasms, lingual thyroid and thyroglossal duct cyst, vascular malformations, dermoid/epidermoid
Visceral	Thyroid lesions; lymphadenopathy; laryngeal masses (squamous cell carcinoma, chondrosarcoma); parathyroid lesions; thyroglossal duct cyst; esophageal diverticulum and neoplasm; abscess and infection
Prevertebral	Discitis/osteomyelitis, metastases, disc herniation, hematoma, secondary extension of tumor from adjacent spaces, vertebral artery dissection/pseudoaneurysm, primary bone tumors, nerve sheath tumors, mesenchymal neoplasms
Posterior triangle (cervical)	Lymphadenopathy, lipoma, nerve sheath tumors, vascular malformations, liposarcoma

[a]The term lymphadenopathy in the above table includes the possibility of the following etiologies: reactive, neoplastic (both metastatic and lymphoma), and suppurative.

in some cases for the sake of simplification and in other cases to reflect surgical anatomy. Table 11.2 lists the more common differential diagnoses that apply to each space. An example of pathology in each space is provided.

Spaces of the Neck

Excluding the orbit and sinonasal region, the soft tissues of the neck can be divided into supra and infrahyoid portions. The suprahyoid neck is divided into spaces by the three layers of the deep cervical fascia (which includes the superficial/investing layer, the middle/buccopharyngeal layer, and the deep/prevertebral layer). In the suprahyoid neck these spaces include the following: the pharyngeal mucosal space (PMS), the retropharyngeal space (RPS), the sublingual space, the submandibular space, the buccal space, the masticator space, the parapharyngeal space, the parotid space, the prevertebral space, and the posterior triangle (cervical) space. Within the infrahyoid neck the major spaces include the carotid sheath, the RPS, the visceral space, the posterior triangle (cervical) space, and the prevertebral space.

Pharyngeal Mucosal Space

The components of the PMS are variably described but include the mucosal surface and submucosa of the oral cavity, nasopharynx, oropharynx, and the suprahyoid portion of the hypopharynx (114). In addition to mucosa, its contents include minor salivary glands, the lymphoid tissue of Waldeyer ring, the pharyngeal constrictor muscles, the salpingopharyngeus muscles, and the pharyngobasilar fascia. Because squamous epithelium compromises the majority of this space, it is not surprising that the most common lesion of the PMS is squamous cell carcinoma. Small lesions may be occult on CT and MRI; imaging is mainly used to characterize the deep extent of mucosal lesions as well as evaluate for nodal metastasis (Figs. 11.1, 11.9, and 11.22).

Retropharyngeal Space

The RPS is a potential space bordered anteriorly by the visceral fascia and posteriorly by prevertebral fascia. The alar fascia divides the RPS into anterior and posterior

Figure 11.28 Retropharyngeal abscess in a 2-year-old male with fever and lymphadenopathy. Axial contrast enhanced neck CT reveals a large rim enhancing retropharyngeal abscess (*arrows*) causing mass effect on the posterior pharyngeal wall (*arrowhead*).

compartments and is not typically seen on imaging. The caudal extent of the space is variable but extends to approximately T4 where the alar fascia and visceral fascia fuse. The posterior compartment of the RPS has been referred to as the danger space because it extends to the diaphragm and can result in direct spread of infection into the posterior mediastinum (112). Within the suprahyoid neck, the RPS contains fat and retropharyngeal lymph nodes. Within the infrahyoid neck, it contains only fat. Few pathologies arise in the RPS. Common abnormalities in this space include edema (secondary to infection, trauma, radiation, longus colli tendinitis), suppurative and metastatic lymphadenopathy, abscess, and direct extension from nasopharyngeal carcinoma (Fig. 11.28).

Sublingual Space

The anterior and lateral margins of the sublingual space are the lingual cortex of the mandible and the posterior margin is the hyoid bone. The superior and inferior borders are the oral mucosa and the mylohyoid muscle, respectively. The mylohyoid muscle acts as a sling to contain the sublingual space. The following structures are included in the sublingual space: paired sublingual glands, the deep portions of the submandibular glands and the submandibular ducts, muscles, the lingual nerve, lingual artery and vein, and cranial nerves IX and XII. Common pathologies of the sublingual space include extension of squamous cell carcinoma, secondary spread of odontogenic infections, and sialolithiasis (Fig. 11.29).

Submandibular Space

The submandibular space is the most inferior space within the suprahyoid neck; its inferior border is the hyoid bone. It lies inferolateral to the mylohyoid muscle and posteriorly

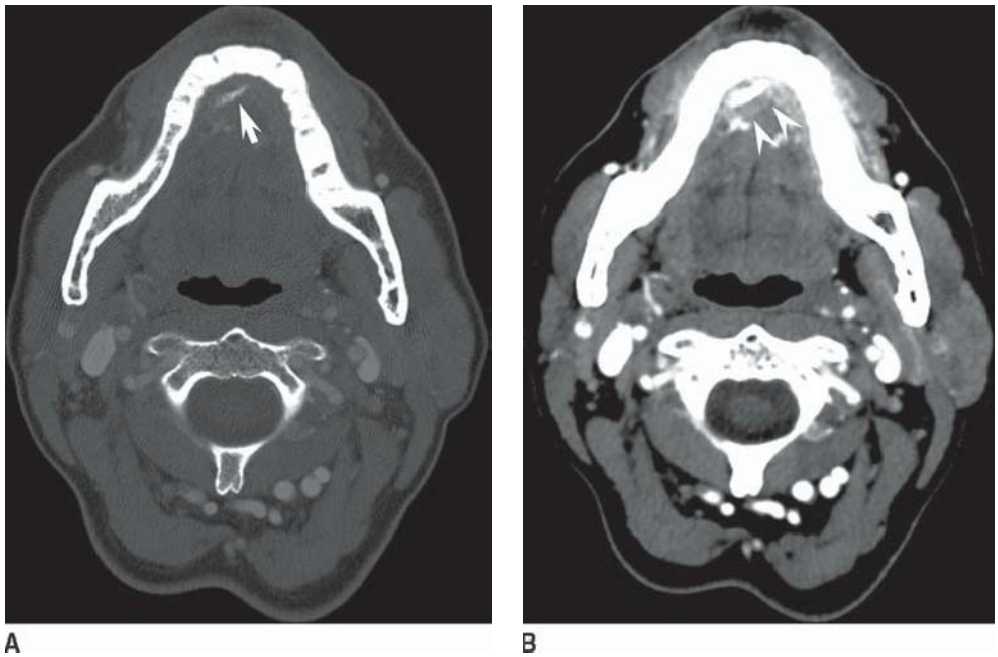

Figure 11.29 Right Wharton duct sialolith and floor of mouth squamous cell carcinoma. **A,B**: Axial contrast-enhanced neck CT. **A:** Bone windows demonstrate a tubular sialolith in the right sublingual space in the distal right Wharton duct (*arrow*). **B:** Soft tissue windows reveal an associated right floor of mouth enhancing squamous cell carcinoma (*arrowheads*) in the right sublingual space.

Figure 11.30 Plunging ranula. Coronal reconstruction from a contrast-enhanced neck CT. There is lobulated low attenuation cystic mass (*small arrows*) within the right submandibular space. The mass flattens the inferior margin of the right mylohyoid muscle. The normal left mylohyoid muscle is clearly seen (*asterisk*). A tubular portion of the mass (*large arrow*) extends from the right sublingual gland. This is a surgically proven plunging ranula.

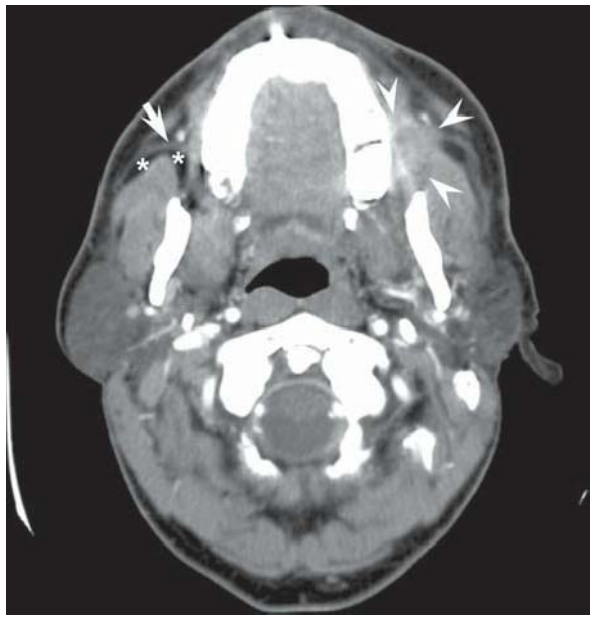

Figure 11.31 Left buccal carcinoma. Contrast-enhanced neck CT. There is a mass (*arrows*) arising from the left buccal mucosa that extends deep into the left buccal space, invading the left buccal fat pad and surrounding distal left Stensen duct. Compare this to the normal distal right Stensen duct (*arrow*) and right buccal fat pad (*asterisk*).

it communicates freely with the sublingual space at the free margin of the mylohyoid muscle. The submandibular space contains the superficial portion of the submandibular gland, level I lymph nodes, the facial artery and vein, branches of cranial nerve XII and the anterior belly of the digastric muscle (114). In adults, common pathology in the submandibular space includes lymphadenopathy, infection, sialolithiasis, and plunging ranula (Fig. 11.30). In children, a second branchial cleft cyst commonly occurs in this space.

Buccal Space

The buccal space consists mainly of adipose tissue and is interposed between the buccinator muscle medially, the superficial muscles of facial expression laterally, and the masticator space posteriorly. In addition to fat, the buccal space includes minor salivary gland tissue, parotid duct, lymph nodes, branches of cranial nerves V and VII, and facial vessels (115). Because it does not have fascia separating it distinctly from the adjacent spaces, infectious and neoplastic processes extend through the buccal space easily. Due to ectopic rests of minor salivary gland tissue, minor salivary gland tumors are a common cause for a primary buccal space mass. Other common pathologies in the buccal space include secondary involvement of squamous cell carcinoma and infection, facial lymphadenopathy and venous or venolymphatic malformation (Fig. 11.31).

Masticator Space

The masticator space is enclosed by the splitting of the superficial layer of the deep cervical fascia and includes the muscles of mastication, the posterior body and ramus of the mandible, the maxillary artery, the pterygoid venous plexus and V3 as it courses through the infratemporal fossa. The superomedial margin of the masticator space is the skull base, directly medial to foramen ovale. Consequently, neoplasms involving the masticator space can extend to the intracranial compartment via perineural spread of neoplasm along V3. Superolaterally, the suprazygomatic portion of the masticator space includes the attachment of the temporalis to the outer table of the calvarium. Inferiorly, the masticator space extends to the attachment of the medial pterygoid and masseter muscles to the mandible (114). In adults, the most common pathology affecting the masticator space is odontogenic infection, though involvement of the masticator space secondarily from metastasis, oropharyngeal and oral cavity squamous cell carcinoma and from skull base pathology are frequent as well (Fig. 11.32). Because much of the masticator space consists of the muscles of mastication, mesenchymal tumors occur in this space, particularly sarcomas in children.

Parapharyngeal Space

The parapharyngeal space extends from the skull base to the level of the angle of the mandible and consists of mostly fat and connective tissue. It lies lateral to the pharyngobasilar

Figure 11.32 Left hepatocellular carcinoma metastasis to the left masticator space. Axial contrast-enhanced neck CT. There is a large avidly enhancing mass (*arrow*) involving the left masseter and medial pterygoid muscles, eroding part of the left mandibular ramus. It displaces the parapharyngeal fat medially (*asterisk*) and extends into the left inferior alveolar nerve canal (*arrowhead*).

fascia surrounding the nasopharynx. There are numerous variations describing the boundaries of this space. It is subdivided into a prestyloid and poststyloid compartment by the tensor-vascular-styloid fascia, a fascia containing fibers from the tensor veli palatini (113). Posterior and medial to the fascial layer is the poststyloid parapharyngeal space, which is also referred to by some authors as the carotid space and contains the contents of the carotid sheath including the internal carotid artery (ICA), internal jugular vein, sympathetic chain, lymph nodes, and cranial nerves IX to XII in the suprahyoid neck (114). Anterior and lateral to the tensor-vascular-styloid fascia is the prestyloid parapharyngeal space, which contains primarily fat but also contains minor salivary gland rests. A small part of the deep portion of the parotid gland protrudes into the prestyloid parapharyngeal space via the stylomandibular tunnel.

MRI and CT can be used to differentiate prestyloid and poststyloid lesions by their position and displacement pattern of the parapharyngeal fat. Most lesions confined to the prestyloid parapharyngeal space are salivary in origin and may arise from the deep portion of the parotid gland or from salivary gland rests (113,116). If there is no fat plane between a prestyloid parapharyngeal space mass and the parotid gland, the mass is usually arising from the parotid gland. Prestyloid parapharyngeal space masses arising from the deep portion of the parotid gland will typically displace the parapharyngeal fat anteromedially toward the pharynx. Prestyloid lesions typically are anterior to the carotid artery and extend anterior to the styloid process. They may pass through the stylomandibular tunnel (Fig. 11.33).

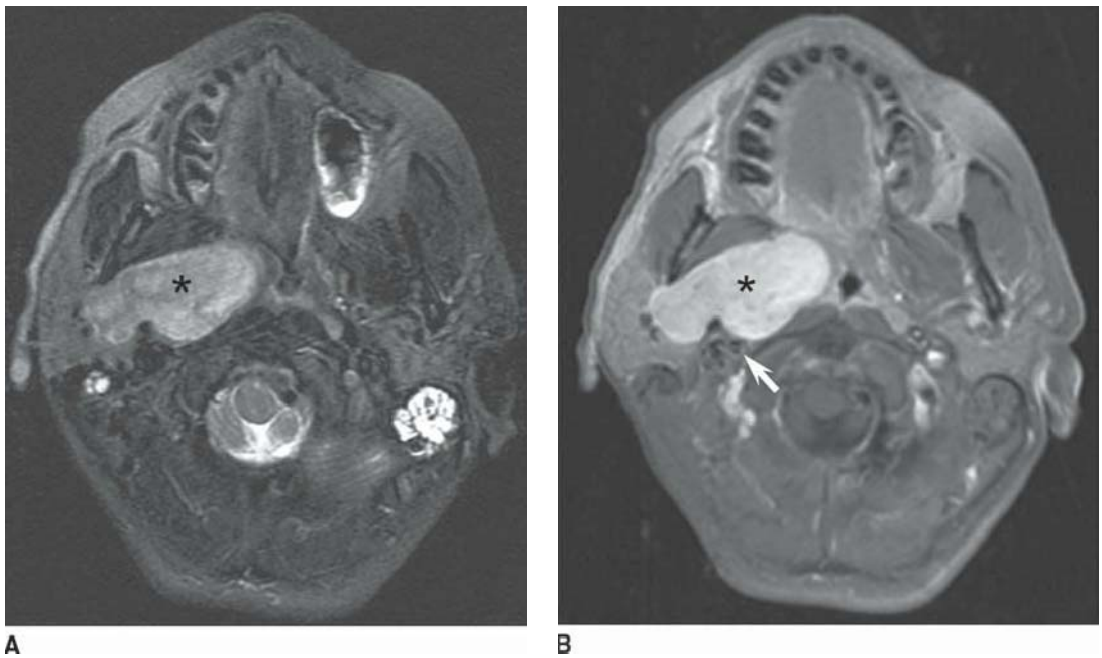

Figure 11.33 Pleomorphic adenoma. **A:** Axial T2 fat suppressed image. A T2 hyperintense pleomorphic adenoma (*asterisk*) arising from the deep portion of the right parotid gland extends through the stylomandibular tunnel into the prestyloid parapharyngeal space. There are incidental bilateral mastoid effusions. **B:** Contrast-enhanced axial T1-weighted image with fat suppression. The mass (*asterisk*) solidly enhances and the right ICA (*arrow*) is displaced posteriorly by the mass. *(conitnued)*

Figure 11.33 *(Continued)* **C:** Axial T1-weighted image. The prestyloid parapharyngeal fat (*arrowheads*) is displaced anteromedially by the mass (*asterisk*).

Poststyloid parapharyngeal space masses tend to displace the parapharyngeal fat anteriorly and laterally. Poststyloid lesions may have a small extension posterior to the styloid process. Similarly, poststyloid masses usually displace the ICA anteriorly (Fig. 11.34). Poststyloid lesions can extend through the jugular foramen. Lesions in the poststyloid parapharyngeal space arise from structures in the carotid sheath as discussed in the next section.

Carotid Sheath

The carotid sheath is an enclosed fascial space with various contributions from the layers of the deep cervical fascia. It traverses the suprahyoid and infrahyoid neck and extends from the skull base to the aortic arch. It contains the internal and common carotid arteries, the internal jugular vein, lymph nodes, fat, and the sympathetic chain. In the suprahyoid neck, the carotid sheath contains cranial nerves IX through XII. In the infrahyoid neck, it contains only cranial nerve X. There is debate in the radiology literature as to whether the suprahyoid portion of the carotid sheath containing the ICA should be included as part of the parapharyngeal space (referred to as the poststyloid parapharyngeal space) or should be designated a separate "carotid space" for the simplicity of a space-based differential diagnosis. The use of the term poststyloid parapharyngeal space referring to the contents of the carotid sheath in the suprahyoid neck is preferred because the tensor-vascular-styloid fascia serves as a surgical boundary between the prestyloid compartment (containing the deep portion of the parotid gland) and the poststyloid compartment (containing the carotid sheath) when approaching the parapharyngeal

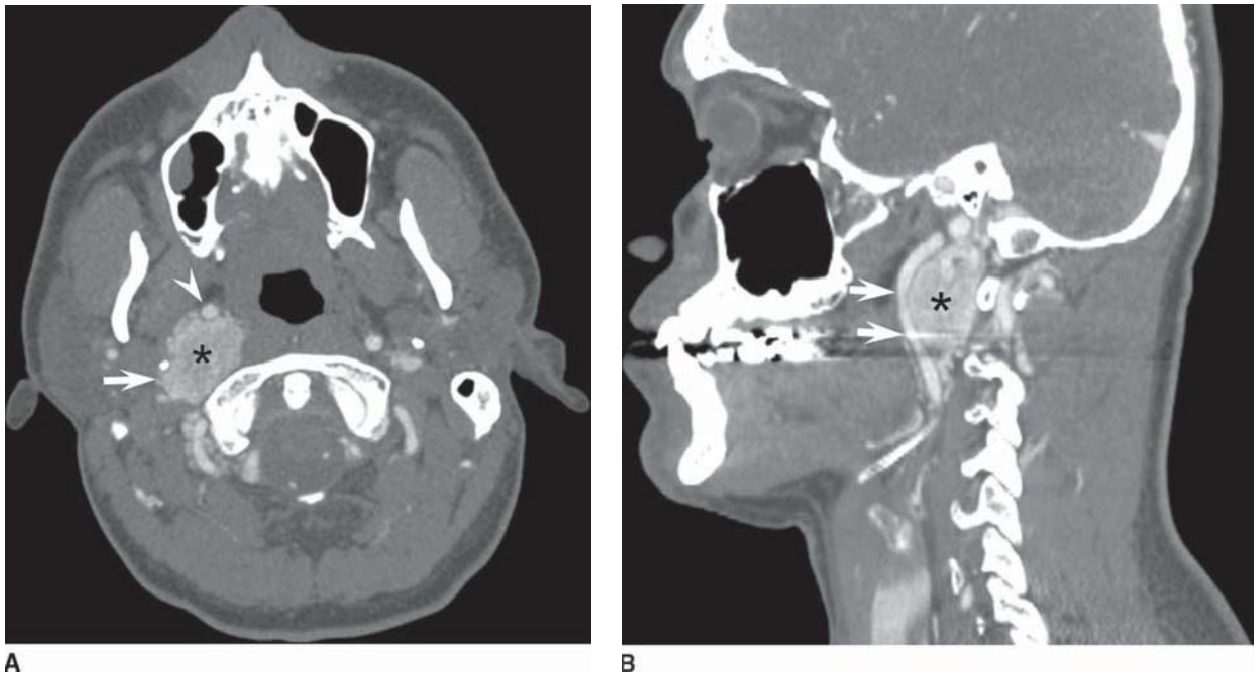

Figure 11.34 Right glomus vagale. **A:** Axial contrast-enhanced neck CT reveals a large avidly enhancing right poststyloid parapharyngeal space mass (*asterisk*) typical of a glomus vagale displacing the right cervical ICA (*arrowhead*) anteriorly. A small portion of the mass protrudes posterior to the right styloid process (*arrow*). **B:** Sagittal reconstruction from contrast-enhanced neck CT. There is anterior displacement of the cervical right ICA (*arrows*) along the anterior margin of the mass (*asterisk*). This is a pathologically proven paraganglioma.

space (117). Common pathology in the carotid sheath includes dissection, pseudoaneurysm, lymphadenopathy, schwannoma, and paraganglioma (Figs. 11.10 and 11.34).

Parotid Space

The parotid space contains the parotid gland as well as the facial nerve, intraparotid lymph nodes, the retromandibular vein, and parts of the external carotid artery (114). The intraparotid portion of the facial nerve is not well seen due to its small size but lies just lateral to the retromandibular vein. The majority of parotid space lesions are primary parotid neoplasms with the most common benign lesion being a pleomorphic adenoma. Inflammatory processes and lymphadenopathy are frequent in the parotid gland as well (Figs. 11.12 and 11.17).

Prevertebral Space

The prevertebral space is enclosed by the deep layer of the deep cervical fascia, which surrounds the vertebra and posterior paraspinal muscles. It attaches to the transverse processes, dividing it into anterior and posterior compartments. The anterior compartment includes the anterior vertebra, the prevertebral muscles and the vertebral vessels. The posterior compartment surrounds the posterior elements and also includes the paraspinal muscles and fat. In the infrahyoid neck, the scalene muscles, brachial plexus, and phrenic nerve are included in the anterior compartment. The majority of pathology arising in this space arises from the vertebra, discs and neural elements and commonly includes discitis/osteomyelitis, metastasis, and less commonly primary bone lesions (Fig. 11.35) (112).

Posterior Triangle (Cervical) Space

The posterior triangle space is between the superficial and deep layers of the deep cervical fascia in the posterior neck and has been referred to by numerous names including the posterior cervical space (118). It is between the sternocleidomastoid muscle anterolaterally and the paraspinal muscles posteromedially. Important structures in the posterior cervical space include cranial nerves XI, portions of the brachial plexus, cutaneous nerves, and level V nodes. Lymphadenopathy, vascular malformations, and lipomas are common in this space (Fig. 11.36).

The Visceral Space

The visceral space is the only space confined to the infrahyoid neck (114). It is circumscribed by the middle layer of deep cervical fascia and contains the thyroid, parathyroid glands, larynx, infrahyoid hypopharynx, trachea, cervical esophagus, paratracheal nodes, and recurrent laryngeal nerves. Pathology in the visceral space reflects the tissues in it and commonly includes squamous cell carcinoma, thyroid lesions, lymphadenopathy, and parathyroid adenoma (Figs. 11.13 and 11.24).

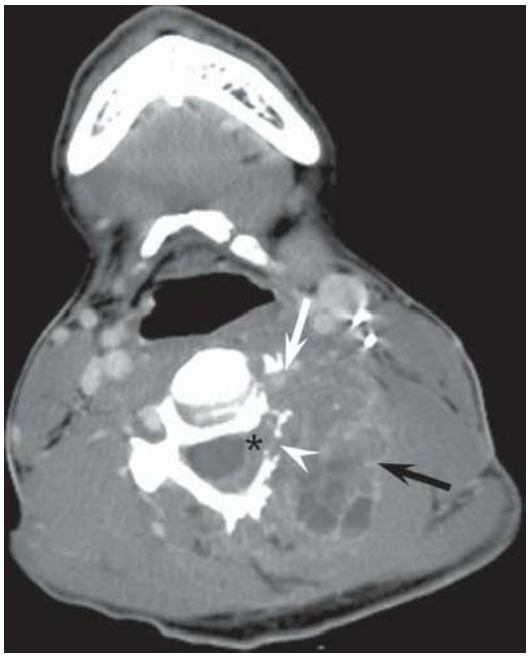

Figure 11.35 Metastatic melanoma. Axial contrast-enhanced neck CT. There is large enhancing mass (*large black arrow*) in the left posterior paraspinal soft tissues encasing part of the left vertebral artery (*white arrow*), eroding part of the vertebral body (*arrowhead*) and extending into the dorsolateral epidural space (*asterisk*). Surgical clips in the left neck are related to a prior neck dissection.

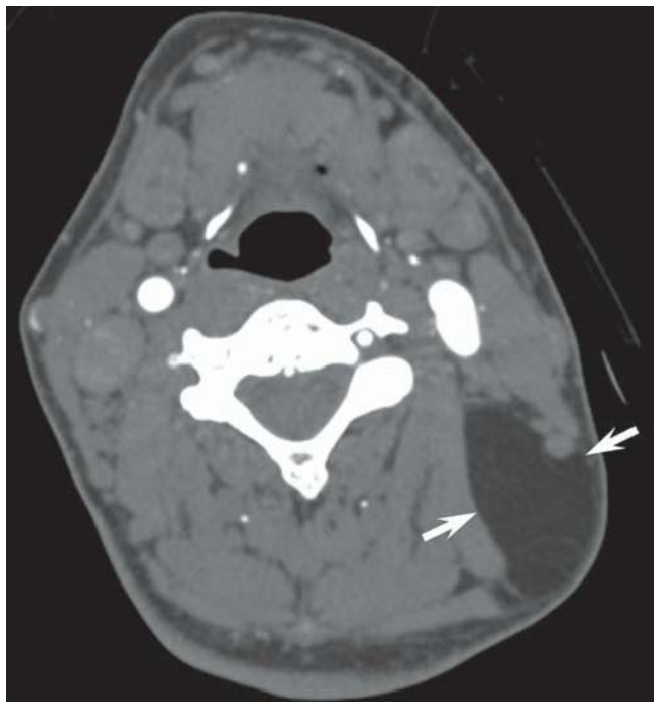

Figure 11.36 Posterior triangle lipoma. Axial contrast-enhanced neck CT. A well-circumscribed fat attenuation mass (*arrows*) in the posterior left triangle interposed between the paraspinal musculature and the left sternocleidomastoid muscle is consistent with a lipoma.

SUMMARY

Cross-sectional imaging plays an invaluable role in demonstrating the deep extent of mucosal lesions and characterizing pathology arising from the other spaces of the head and neck. CT and MRI are often complimentary, particularly in evaluating skull base pathology. Nuclear medicine studies provide complimentary functional and metabolic information, but lack good spatial resolution. The best choice of imaging modality and technique is dependent on the clinical question and emphasizes the importance of communication between radiologists and clinicians to provide the best care for the patient.

HIGHLIGHTS

- Contrast-enhanced CT is frequently the first study of choice for evaluation of an adult palpable neck mass. MRI offers better soft tissue contrast, but for practical reasons should be used to address specific questions or problem solve.
- Noncontrast neck CT is preferred for evaluation of sialolithiasis.
- CT and MRI are complimentary in the evaluation of skull base pathology. CT better demonstrates fine bony detail and MRI better characterizes marrow space disease, perineural spread of neoplasm, and intracranial extension of disease.
- Ultrasound is typically the first study of choice for evaluation of a palpable pediatric neck mass and for evaluating thyroid pathology. It is useful to evaluate for metastatic cervical lymph nodes in patients with thyroid cancer, characterize vascular lesions, differentiate cystic from solid lesions, and guide biopsies.
- PET/CT is the study of choice for staging patients with advanced HNSCC because it has greater sensitivity than conventional imaging modalities. It may be useful in cases of unknown primary neoplasm, radiation treatment planning, monitoring treatment response, and surveying for disease recurrence. It has a high negative predictive value for residual or recurrent disease in patients treated for HNSCC.
- In patients treated for differentiated thyroid carcinoma, whole body radioactive iodine scan, in conjunction with cross-sectional imaging of the neck, is useful to survey for recurrent or residual disease. PET/CT is reserved for patients with clinical evidence of disease recurrence and a negative posttreatment whole body I-131 scan.
- Ultrasound and parathyroid scintigraphy are currently the studies of choice for localization of parathyroid adenoma in patients with hyperparathyroidism. The sensitivity of ultrasound and parathyroid scintigraphy is suboptimal for multiglandular disease. 4-D-CT is a promising new tool for localization of hyperfunctioning parathyroid tissue, but currently is primarily used in cases of failed prior surgery or equivocal ultrasound and parathyroid scintigraphy results.

12 Surgical Pathology in Otolaryngologic Practice

Matthew C. Miller *Christa L. Whitney-Miller*

A thorough understanding of pathology is essential to any surgical practice. Each day, the surgeon is faced with numerous scenarios that necessitate consultation with the pathology laboratory. The pathologist is consulted to interpret biopsies, to provide staging data, to assess surgical margins, to confirm clinical diagnoses, and, ultimately, to collaborate with the surgeon in a manner that allows for well-informed management decisions. Unfortunately the collaborative nature of this relationship is at times disregarded. As a consequence, our colleagues in pathology may be asked to make their assessment in a vacuum—devoid of potentially important clinical or surgical data. The degree to which the pathologist is informed of the clinical question can have a profound impact upon specimen preparation and interpretation. Conversely, if the surgeon does not have an understanding of specimen handling and preparation, he or she may unwittingly compromise the pathologist's ability to answer a given clinical question.

The aim of this chapter is to introduce the otolaryngologist to the general principles of anatomic pathology and to provide a framework for obtaining and interpreting pathologic data. Though the pathologic findings of specific diseases are discussed and exemplified in the text and accompanying atlas, this is in no way meant to be an exhaustive review of head and neck histopathology. A significant proportion of the materials herein are devoted to head and neck oncologic surgery as pathology plays a vital role in the management of head and neck tumors. However, the principles outlined are applicable to the other areas of otolaryngology as well.

BIOPSY TECHNIQUES

A common outpatient scenario involves the otolaryngologist evaluating a patient with a head and neck mass. Once the appropriate history and physical examination have been performed, the next step typically involves obtaining tissue for diagnosis.

The techniques employed for biopsy vary depending upon the site, size, and character of a particular mass. Atraumatic and meticulous technique is paramount and failure to properly handle a specimen can limit the quality and quantity of the data gleaned from the biopsy. This is true for samples procured from epithelial surfaces and from those obtained percutaneously.

Biopsy of Cutaneous and Mucosal Surfaces

In the context of a cutaneous lesion, incisional or excisional biopsies may be performed. Shave biopsies are generally not recommended as an accurate assessment of tumor thickness cannot be made using this technique. This is of particular importance with pigmented lesions since staging and subsequent therapy of malignant melanoma is dependent upon the depth of invasion (1). In addition, the dermatopathologist cannot differentiate between carcinoma *in situ* (CIS) and invasive carcinoma without evaluating the basement membrane—a feature that cannot be assessed on scrape biopsies.

The simplest and most efficient means of obtaining a skin sample is through the performance of a punch biopsy. A variety of skin punches are commercially available and typically range in size from 2 to 4 mm in diameter. These instruments are typically trephines attached to the end of a long plastic handle. The blade is inserted perpendicular to the skin and gently rotated through the epidermis and the dermis as to provide a full-thickness sample of the lesion in question. For all but the smallest lesions, punch biopsies are incisional rather than excisional. Thus a more definitive procedure will often be required once the diagnosis is confirmed. Alternatively, skin lesions may undergo incisional biopsy or, if small enough, be excised *en bloc* with a scalpel in the outpatient clinic. Care must be taken to orient

excisions within the relaxed skin tension lines within the face and neck.

When obtaining tissue from mucosal sites in the upper aerodigestive tract, through-cutting or cupped forceps are often employed. Using this method, a representative portion is grasped with the instrument and sharply divided or avulsed from the lesion in question. Though widely used, this forceps biopsy does have its drawbacks. The urologic literature suggests that this technique may result in inaccurate diagnosis due to limited sample size, distorted architecture, and crush artifact (2). In addition, the samples tend not to be full thickness. Consequently, the pathologist may not be able to differentiate *in situ* from invasive carcinoma. Conversely, incisional/excisional scalpel biopsies and punch biopsies allow for a more complete assessment of a mass, its interface with the surrounding tissue, and, in the context of malignancy, the depth of tumor invasion—a feature that has significant treatment implications for early-stage oral cavity tumors. Moreover, it has been demonstrated that when compared to other methods, oral biopsy samples obtained using a punch are significantly less prone to artifacts such as crushing, splitting, hemorrhage, and fracture—all features that might impede the pathologist's ability to make a complete and accurate assessment (3). Given all of this information, it is the authors' contention that punch biopsy be the first choice for mucosal biopsy in the upper aerodigestive tract and that the cup forceps should only be used when punch or scalpel biopsy is not technically feasible (i.e., due to inaccessibility because of the anatomic locale, trismus, or other factors).

Biopsy of Subcutaneous Masses

Neck masses are among the most common reasons for referral to otolaryngologist–head and neck surgeons. An understanding of percutaneous biopsy techniques is essential to their management. The most common method for obtaining tissue diagnosis in the context of a neck mass remains the fine needle aspiration (FNA) biopsy. FNA has long been central to the diagnostic algorithm for thyroid nodules. It has also assumed a prominent role in the evaluation of enlarged cervical lymph nodes, salivary masses, and other subcutaneous tissues. FNA is relatively simple to perform in the outpatient setting, it is safe and well tolerated by most patients without the use of local anesthesia, and is highly accurate when used appropriately. Indeed, a recent meta-analysis by Tandon et al. (4) revealed that the aggregate sensitivity, specificity, positive, and negative predictive values across all head and neck subsites were 89.6%, 96.5%, 96.2%, and 90.3%, respectively. Despite its benefits and widespread use, there is no consensus as to the optimal technique for specimen acquisition and preparation. In addition, most otolaryngology programs do not formally train residents to perform FNA—oftentimes leaving them unaware of the potential pitfalls in performing the procedure. This has likely contributed to the high rates of specimen inadequacy that have been observed in some contexts (4–7).

Failure to obtain adequate tissue for cytologic analysis remains a vexing problem in clinical practice. Several studies have addressed this issue and the means by which the rates can be improved. The process begins with using the appropriate equipment. It is recommended that either a 23 or 25-gauge needle of adequate length be employed for FNA (8). In the authors' experience, the 25-gauge needle is of sufficient caliber to obtain a specimen while at the same time minimizing patient discomfort. The authors use a modification of the technique described by Dusenberry (8): After decontaminating the skin with an alcohol wipe, the tip of the needle is passed into the center of the mass. A "series of short, staccato strokes" are performed while holding continuous suction on the plunger (among head and neck masses, active suction during aspiration appears to yield significantly higher rates of specimen adequacy when compared to needle strokes without suction (9)). The procedure is continued until material is observed within the hub of the needle. At this point, the aspiration should stop and the needle should be withdrawn from the skin. If a cystic lesion is encountered, it should be completely evacuated in order to reduce the risk of a false-negative aspiration—particularly when nodal metastasis is in the differential diagnosis. Once the sample is collected, a smear is made of the aspirate and it is prepared for the pathologist. If lymphoma is suspected, additional material should be placed into a specialized transport material and submitted for flow cytometry.

If sufficient material is available, a cell block may also be prepared. A cell block is a means of preparing an FNA specimen that allows it to be processed, sectioned, and stained as if it were a histology section. Cell blocks are prepared from small tissue fragments, blood clots, and mucus within the FNA needle. This material is then compacted into a "block" for further processing. Cell blocks can be made manually, with albumin or agar, and with or without the aid of centrifugation. The cell block is a valuable tool in that it can supplement the information gathered through cytologic smears. Additionally, special stains (including immunohistochemistry [IHC]) can be performed on cell blocks (10).

After aspiration and smearing, slides are allowed to air dry or are placed into 95% ethanol for Papanicolaou staining. Air-dried slides may be evaluated on-site using Diff-Quik staining. The Diff-Quik stain may be performed within minutes of specimen procurement and allows for immediate examination by the cytopathologist. On-site evaluation is not simply for establishment of an "on the spot" diagnosis. Rather its value is in the determination of specimen adequacy. The importance of this practice cannot be understated. In essence, it provides the physician with immediate confirmation that an appropriate amount of the desired material was collected—thereby decreasing

the likelihood that the patient will be subject to the discomfort, distress, and expense of rebiopsy. A 2010 report by Moberly et al. supports this notion. They found that both the rates of specimen adequacy and the ability to obtain a definitive diagnosis by FNA were improved by immediate cytologic analysis (7). Given these findings, it is recommended that whenever feasible, a cytotechnologist or cytopathologist be present during performance of an FNA so that they may assess the specimen for adequacy.

The addition of image guidance also appears to have a significant effect upon the success of FNA. Early experience with CT and ultrasound-guided biopsy yielded favorable results—with these techniques being utilized to improve needle placement and diagnostic yield during FNA, even in the presence of palpable disease. Due to the reduced cost, lack of radiation exposure, improved sensitivity, and widespread availability of ultrasound, it has to a great extent supplanted CT for use in image-guided biopsy. Indeed, office-based ultrasound is now employed by a growing number of otolaryngologists and is particularly useful for assisting with needle placement. When compared to the traditional palpation method of needle placement, ultrasound-guided FNA has been shown to reduce the number of false-negative biopsies (11) and improve the diagnostic accuracy and adequacy rates by 23% and 84%, respectively (12). Surgeon-performed ultrasound-guided FNA appears to yield similar results to those achieved by interventional radiologists and cytopathologists. A randomized controlled trial conducted by Robitschek et al. (6) found that the number of inadequate specimens decreased by nearly 30% when ultrasound was utilized to perform FNA in the otolaryngology clinic.

While FNA yields cellular material suitable for cytologic characterization, the technique does not preserve tissue architecture—a feature that may reveal additional clues as to the definitive diagnosis. Core biopsies, on the other hand, provide a more substantial and intact piece of tissue that may be fixed and stained for review by a surgical pathologist. Core biopsies are generally performed using larger bore needles (18 or 20 gauge) than those used for FNA. There are a number of commercially available devices for core needle biopsy. These typically consist of a spring-loaded mechanism that deploys the needle once a trigger is depressed. The needle enters the specimen and is rapidly withdrawn, taking with it a core of tissue that may subsequently be fixed and processed by the histology laboratory. Alternatively, core needle biopsy may be performed using a standard needle and syringe, making a single swift pass into and out of the lesion in question. Given the size of the needle, local anesthetic is often injected into the overlaying skin in order to minimize discomfort. A small skin incision may also be made to facilitate needle entry without contamination by the overlaying epidermis.

Though core biopsy is common in non–head and neck sites, it has yet to gain widespread popularity for our purposes. This may be due to concern regarding bleeding and trauma to structures such as the facial nerve and great vessels as these complications have been reported (13). However, larger studies specifically addressing head and neck biopsies have demonstrated complication rates similar to those reported for FNA (14–17). Another concern regarding head and neck core biopsy is that it may have the potential to seed tumor cells along the needle tract—though this has not been shown to be the case (18).

Moreover, Saha et al. (19) demonstrated that ultrasound-guided core needle biopsy was significantly more accurate than palpation-guided FNA at detecting cervical metastases (97% vs. 85%) and that seeding was not an issue. Among their series of 49 core biopsies and 50 FNAs, the nondiagnostic rates were 2% and 42%, respectively. The data is somewhat misleading given the fact that FNA was performed without ultrasound guidance. However, this and other similar studies do suggest that in skilled hands and with image guidance, core needle biopsy is a safe and useful tool in the evaluation of head and neck masses. It has been promoted as a less traumatic, less time consuming, and more easily performed alternative to open biopsy in the context of a neck mass. As such, core biopsy may be best suited as in an intermediate step between FNA and surgical exploration in patients with nondiagnostic or indeterminate cytology (14,15).

PATHOLOGY AND THE OPERATING ROOM

The appropriate management of surgical specimens within the operating room is a highly active and interactive process that involves the surgeon, operating room staff, laboratory personnel, and pathologist. In order to obtain meaningful information from the pathologist, surgeons must be intimately involved in this process both before and after the specimen leaves the back table. Implicit in this should be awareness that certain behaviors and operative maneuvers can have profound effects upon the pathologist's interpretation of the tissue being sent to them. Understanding these actions and the proper techniques for handling operative specimens will effectively minimize ambiguity in the interpretation of surgical margins, optimize the use of frozen sections, and maximize the accuracy of pathologic data.

Surgical Margins: Adequacy

In head and neck cancers (and in some benign diseases such as pleomorphic adenoma) margin status has long been known to affect subsequent treatment and ultimately prognosis. Both locoregional control and overall survival may be compromised in the context of grossly or microscopically positive margins. Using relatively nonstringent criteria for margin positivity (defined as frank carcinoma, CIS, or premalignant change at the margin), Loree and Strong (20) found that the incidence of

local recurrence increased twofold and that the survival rate was reduced by 13% in patients with positive surgical margins. The absolute distance from a margin is also of importance in head and neck cancers. Nason et al. (21) evaluated patients with margins that were 5 mm or more, 3 to 4 mm, 2 mm or less, and clearly involved. In their series of 277 patients with oral cavity carcinoma, there was a highly significant difference in overall and recurrence-free survival that varied with the size of the margin. After matching for stage and other confounding variables, patients with positive surgical margins had a 2.5-fold increase in risk of death at 5 years when compared to patients with negative but close (3-mm) margins. Patients with 3-mm margins had a 1.5-fold increase in risk of death compared to those with clear (greater than or equal to 5 mm).

Despite the findings of these and similar studies, there currently is no consensus in the literature as to what constitutes an adequate margin for head and neck squamous cell carcinomas (SCCs). Meier et al. surveyed members of the American Head and Neck Society in 2005. Of the 476 responses, the most common definition of a clear margin was greater than 5 mm. Though this was the most frequently used distance, it accounted for less than 50% of the total responses in the study—reflecting the significant diversity of definitions used throughout the literature and applied in clinical practice. This is further confounded by the fact that 14% of the participants considered CIS to be a negative margin while nearly 26% considered dysplasia to be a positive margin (22). Given the inconsistencies in the literature, it is imperative that individual cases be discussed at multidisciplinary tumor boards with consistent application of local standards and frequent re-evaluation of outcomes and practice patterns.

Surgical Margins: Orientation

Regardless of what standard is chosen, an understanding of how the pathologist evaluates margins will ultimately assist in clinical decision making. When a specimen is received, it is initially fixed in buffered formalin. The tissue is then examined grossly and measured. It is then marked at critical points and presumed margins with one of a variety of commercially available inks or dyes. These inks withstand the fixation and slide preparation process and are visible to the pathologist on light microscopy. Under the microscope, the distance between disease and ink is measured by the pathologist and reported. This essentially is how margins are assessed. However, procedures for specimen inking vary from institution to institution and from pathologist to pathologist. When coupled with the complexity of head and neck anatomy and the fact that excisions often do not obey true anatomic boundaries, the subjective nature of the inking process can confound margin interpretation. This makes communication between the surgeon and the pathology team paramount.

Along these lines, it is vital that the surgeon provide an adequate clinical history and description of the procedure. The pathologist may not have a detailed understanding of otolaryngologic procedures. For example, surgeries such as partial laryngectomy and tongue base resection can be quite foreign to nonsurgeons and involve three-dimensionally complex anatomy. The resulting specimens are often small and amorphous without any identifiable orienting landmarks or directionality. Large specimens such as composite resections or laryngopharyngectomies present another problem as it is not feasible to histopathologically examine the entire surface. In the absence of input from the surgeon, the pathologist must essentially make an educated guess as to what or where the true resection margin is in these cases. Hand delivering a specimen to the pathologist and orienting it for their team can help to minimize ambiguity in margin determination.

It may also be helpful for the surgeon to ink specimens himself or herself. This will ensure that the precise area of concern is being evaluated by the pathologist. Methylene blue is the author's preferred ink for this purpose as it is readily available in most operating rooms and can be easily applied using a cotton-tipped applicator. It should be noted that methylene blue is water soluble—hence the site must be reinked once it reaches the histology laboratory to avoid being washed away during processing. Though little has been written about surgeon-initiated inking in otolaryngology, the breast surgery literature suggests that it is indeed a valuable tool. Numerous studies have implicated surgeon inking as a means of reducing discrepancies and ambiguity in the identification of tumor margins. They have also detailed the shortfalls of suture orientation and the benefits of well-orchestrated specimen handoffs to the pathology team in this regard (23–25).

The inadequacies of contemporary margin procurement and analysis for head and neck surgery have been elegantly discussed by Black et al. (26). Framing this issue in the larger context of quality improvement in medicine, the authors applied a business model—governed by what are commonly known as the "Toyota" principles—to the process. Under this model, processes and production are subdivided into multiple steps with the ultimate goal of reducing redundancy, waste, and error. Each step is carefully regulated and a strong emphasis is placed upon the quality of "handoffs"—the points at which a product is transferred to another team member for performance of the next step. Black's paper highlights the fact that inconsistencies and discrepancies with respect to tumor margins can in large part be attributed to poor communication during handoffs. They contend that interdisciplinary communication must occur earlier in the overall process of margin determination—with the greatest benefit coming at the specimen orientation step. If the process fails at this step, then all subsequent steps and, eventually, the final pathology report, are jeopardized. With this in mind, it is again strongly advocated that the surgeon play an active role in specimen handoff and orientation.

Yet even when all of these measures are taken, we may still be left with a positive margin. However, surgeon-directed orientation—either by intraoperative inking or through a face-to-face handoff to the pathology team—should make the task of re-excision or targeted radiotherapy less daunting.

Surgical Margins: Shrinkage

Typically a head and neck resection is outlined on the tissue surface with a wide margin. However, it is not uncommon to see an assumedly appropriate cuff of normal tissue wither down to no more than a few millimeters once the specimen is excised. This margin may be even smaller by the time the pathologist reviews the slides and renders his or her report. While there may be multiple reasons for discrepancies between gross margins and those observed histologically, specimen shrinkage appears to play a major role. Most shrinkage appears to occur immediately after resection. It is thought to be the result of unopposed contractility in the submucosal musculature and release from surrounding supporting structures (27). In a 1996 study of canine oral mucosa, Johnson et al. demonstrated that specimen margins were reduced by 30% to 47% between the time of excision and the time of histologic review. The majority of shrinkage occurred after resection and before fixation (27). Subsequent to this, Mistry (28) presented a series of patients with SCC. In this report, 1 cm *in situ* margins were measured by the surgeon. Tumors were removed along this margin using monopolar cautery. The margin was subsequently remeasured on the specimen 30 minutes after resection. The overall mean margin shrinkage was 22.7%, with T1 and T2 tumors experiencing significantly greater rates of shrinkage than T3 and T4 tumors (25.6% vs. 9.2%). Similarly, Cheng et al. (29) demonstrated significantly increased shrinkage rates among T1 and T2 tumors as compared to T3 and T4 disease. This might have significant implications for adjuvant therapy as it is commonplace to use margin adequacy to guide adjuvant therapy—particularly in early-stage disease. Tumor location may also play a role in the degree of shrinkage, as the effects appear to be most marked in the buccal mucosa, mandibular alveolar ridge, and retromolar trigone (29). Knowing that significant shrinkage may be anticipated when resecting small tumors in these areas, the surgeon should—being mindful of the functional consequences—plan accordingly and design wider (i.e., greater than 1 to 2 cm) margins.

When discussing margin shrinkage, it is important to recall that prognostic statistics pertaining to margin status are based upon histopathologic data and not *in situ* or gross margins. Thus it is a fallacy to believe that because of shrinkage a close or positive margin may be disregarded as artifact in the context of a wide clinical margin.

Surgical Margins: The Influence of Surgical Technique

The choice of surgical instruments may also influence the pathologist's interpretation of margins. While "cold steel" has for generations been the standard for surgical incisions and excisions, a number of new technologies and instruments—such as the monopolar cautery pencil, the CO_2 laser, and the harmonic scalpel—have been introduced for this purpose. These have been variably touted for their improved hemostasis, reduced operative time, and positive effects on wound healing and postoperative pain (30,31). However, what is often lost in these discussions is the fact that each technique can impart artifactual changes to the tissues. As these artifacts can interfere with the interpretation of margins, it is helpful to inform the pathologist about which technique was used for the resection. Monopolar cautery can induce significant thermal injury and has been shown to induce a wider area of tissue damage when compared to CO_2 laser excision (31,32). Both monopolar and laser techniques result in vacuolar degeneration and nuclear elongation. The nuclei may appear pyknotic and distorted—features that can be confused with dysplasia or even overt carcinoma. If the laser is used, the thermal effects may be reduced using the pulse-wave mode. Likewise, the harmonic scalpel results in fewer artifacts than monopolar cautery, but significantly more than cold steel technique. In comparing these methods, Kakarala et al. showed that harmonic scalpel resulted in significantly less tissue fragmentation and nuclear change than the monopolar. However, the scalpel was superior to both with respect to margin distortion (30). Though the histologic benefits must be weighed against other factors such as bleeding, it is recommended that any surface being evaluated as a resection margin be incised using cold sharp technique.

PRACTICAL USE OF FROZEN SECTIONS

Frozen section is a technique in which a small portion of tissue is frozen, allowing for it to be cut, stained, and analyzed without the time-consuming fixation/dehydration process that is required for routine specimens. Using this method, a small tissue sample can typically be prepared and interpreted within 20 minutes from time of receipt in the surgical pathology laboratory. The rapidity and accuracy of intraoperative consultation allows for immediate changes in patient management. In the head and neck, it is a useful tool for establishing a definitive diagnosis, determining margin adequacy, differentiating between benign, malignant, and nonneoplastic masses, evaluating lymph nodes for the presence of metastatic disease, determining the adequacy of a tissue sample, establishing the need for special tissue handling—as in the case of lymphoma, granulomatous, or infectious disease, and for verifying the identity of organs such as the parathyroid glands

(33). Patterns of frozen-section usage are highly variable and are dependent upon the surgeon and the procedure. Nearly all respondents to a recent survey of the American Head and Neck Society reported using frozen sections to evaluate resection margins for oral cavity and oropharyngeal tumors (97% and 91%, respectively). Among this same group of surgeons, fewer than half obtained frozen sections during parotidectomy, thyroidectomy, or sinonasal/skull base resections (22). These patterns are likely to reflect differences in training and local customs. Each individual otolaryngologist's practice should be commensurate with his or her training and the expertise/experience of the surgical pathologist.

Perhaps the most frequent application of frozen section in otolaryngology is in the evaluation of surgical margins. This is evidenced by the fact that 99% of respondents in the American Head and Neck Society survey utilize the test for this purpose (22). The method for procuring margins varied among those polled. Though most reported obtaining samples from the resection bed, 24% took frozen samples from the primary specimen at least part of the time. The advantage of taking frozen-section specimens from critical areas of the resection bed is that it allows for more precise localization of the sample site in the event of a positive margin. And while there is no standard method for obtaining frozen-section samples, there is likewise no standard method for margin analysis by pathologists. This again underscores the need for open communication between the surgeon and the pathologist. The pathologist must be made aware of the surgeon's practices and preferences with respect to margin procurement. Without this interaction, there are likely to be discrepancies between what the surgeon and the pathologist believe to be the status of the margins (26).

Regardless of the sampling method, it appears that frozen section is highly sensitive, specific, and accurate for the determination of tumor margins in the head and neck. In the largest series examining frozen section for this purpose, DiNardo et al. (34), found that the test was 88.8% sensitive, 98.9% specific, and 98.3% accurate in identifying a positive resection margin. However, in an era of medical cost containment, it follows that frozen section should be reserved for circumstances where there is a significant likelihood that it will alter intraoperative management.

Handling of Cervical Lymph Node Specimens

Cervical lymph node excision is one of the most common procedures performed by otolaryngologists. Whether this is in the context of a diagnostic biopsy or a neck dissection, the quality and quantity of information in the pathology report can be significantly affected by specimen handling in the operating room. This is perhaps no more evident than in the context of a suspected lymphoma. If a lymphoproliferative disorder is in the differential diagnosis, the lymph node (or Waldeyer ring tissue) should not be placed into a fixative solution. Instead, it should immediately be sent to the surgical pathology laboratory "fresh"—with the concern for lymphoma clearly indicated on the requisition. The fresh tissue should be hand delivered to the laboratory immediately as fixation, time, and heat will result in protein denaturation. If target antigens denature, the accuracy of flow cytometry may be limited. Furthermore, flow cytometry requires that specimens be separated into individual cells. This allows them to freely flow through the analyzer during characterization. The fixation process makes it difficult to separate the cells from one another—thus making flow cytometry an impossibility. It is important to remember that most flow laboratories only operate during business hours (i.e., Monday to Friday day shift). Specimens that are allowed to sit all weekend or even overnight may significantly degenerate and produce less than optimal results. Hence the surgeon must make the pathology team aware if such a biopsy is being performed at night or on weekends. Many hospitals have established "lymphoma protocols" whereby the specimen cup is explicitly labeled as a possible lymphoma. This initiates the above-mentioned cascade of procedures in an attempt to systematically reduce misadventures in processing.

Neck dissection presents different challenges with regard to specimen handling. In the context of head and neck cancers, a great deal of prognostic information may be derived from histologic evaluation of the cervical lymph nodes. Data such as the number of involved nodes, their location (i.e., level), and the presence or absence of extracapsular extension are used to determine whether or not a patient would benefit from adjuvant therapy and, in some cases, what that therapy might consist of (35,36). Knowing the precise level(s) of involvement may also point to the origin of an unknown primary tumor (37). The absolute number of lymph nodes collected and evaluated also appears to be important. During selective neck dissection for early-stage disease, the likelihood of identifying cervical metastases increases when the total nodal yield is in excess of 20 (38). A 2011 report by Ebrahimi et al. takes this one step further—finding that a nodal yield of less than 18 during elective neck dissection for oral cavity cancers resulted in a significant reduction in overall survival. Though the study does not detail the patterns of failure, a plausible explanation is that these patients were initially understaged at the nodal level and hence undertreated. The authors argue that the minimum number of lymph nodes evaluated during selective neck dissection be 18 (39). This points to the fact that the pathology report should be carefully scrutinized after neck dissection with attention to the total node count. If the 18 lymph node benchmark is not reached, additional therapy may be warranted. In addition, the pathologist should be asked how nodes are counted in their laboratory as this varies from institution to institution. In most, nodes are grossly identified and removed from the fibrofatty tissue after the specimen is received. They are then counted, submitted into individual cassettes,

embedded in paraffin, and analyzed under the microscope. The remaining tissue is typically submitted separately for histologic examination—allowing for the identification of microscopic lymph nodes.

The American Head and Neck Society and American Academy of Otolaryngology–Head and Neck Surgery have convened a task force with a primary goal of standardizing neck dissection classification and nomenclature. This has become increasingly important in the era of selective neck dissection. In recognizing the ambiguity of certain terminology and the difficulties associated with reorienting a nodal packet once it reaches the pathology laboratory, the task force has established guidelines for specimen submission. They recommend that neck contents be divided into levels and sublevels by the surgeon in the operating room immediately after the specimen is removed from the patient. Each level should be carefully placed into a separate container and labeled appropriately. Using this methodology, the risk of misidentifying the neck levels should be minimized (40).

THE PATHOLOGY LABORATORY

To many otolaryngologists, the pathology laboratory is a "black box"—a specimen is sent and sometime later (never fast enough) the results appear in the patient medical record. However, pathology departments are typically among the largest and busiest in both community and academic hospitals. Pathology departments typically consist of two main divisions—anatomic and clinical pathology. Anatomic pathology divisions deal with tissue diagnoses while the clinical pathology laboratory deals with testing of nontissue specimens (i.e., blood chemistry, coagulation testing, etc.) Most anatomic pathology divisions have subdivisions including surgical pathology and cytopathology; some may also have neuropathology, medical (autopsy) pathology, and even molecular pathology laboratories. Many departments also have a separate hematopathology division, which may be part of anatomic or clinical pathology. In addition to the pathologists, there are numerous layers of professional staff and technicians working to prepare and analyze specimens. It is helpful for surgeons to familiarize themselves with the structure and personnel within their local pathology department. This can facilitate the transfer of information and will most certainly promote collegiality and collaboration.

Specimen Handoff and Processing

The importance of communication between surgeon and pathologist has been outlined above and need not be further belabored here. For most routine specimens, this communication may be in the form of an appropriately completed requisition. One should view the pathology requisition as they would any other consultation request. It should pose a clinical question and provide any supporting data or information that might facilitate the expert opinion of the consultant. As such, the clinical history should include the patient's symptoms, differential diagnosis, any prior diagnoses, and/or treatment. Though we expect objective and unbiased assessments, it is important to remember that clinical information helps to frame the pathologist's interpretation of the tissue that they are examining. It may also lead him or her to perform special stains or other tests that they might otherwise not pursue. For instance, clinical suspicion for lymphoma should be clearly stated so that the appropriate tests may be performed. If infectious processes are suspected, this should also be explicitly indicated. This will facilitate use of the appropriate culture media and will serve to warn the pathology team of any potential exposure risks so that they may take the appropriate precautions (as in the case of *Mycobacterium tuberculosis*, for instance).

Prompt placement into fixative is of considerable importance (provided infection and hematologic malignancy are not under consideration). Tissue that is not fixed promptly may show marked drying or degenerative changes, making accurate diagnosis difficult or even impossible. Fixation is a chemical process which prevents this decay and increases the mechanical strength and stability of the tissues (10). The most commonly used fixative in today's surgical pathology laboratories is neutral buffered formalin (NBF). NBF is 3.7% formaldehyde in phosphate buffered saline. The formaldehyde acts by cross-linking proteins. NBF is inexpensive and compatible with most special stains, including IHC (41). The volume of NBF should be at least 10 times that of the tissue sample, and the sample should be completely surrounded by fixative (specimens that float and sink should be wrapped in Telfa or gauze to ensure that they are completely submerged and fixed evenly). Formalin penetrates at a rate of approximately 1 mm/h and tissue must be fixed through before it can be processed. In small biopsy specimens, this will happen in a matter of hours and the specimen can be processed later that day or the next. Larger specimens benefit from additional cuts into the tissue in order to allow for quicker penetration and fixation. The largest most complex specimens (such as laryngectomies and composite resections) may require multistep dissection with interval fixation. Those that contain bone will require decalcification, which can take several days itself, depending on the thickness of the bone. Fixed specimens are subsequently embedded into paraffin blocks. The blocks are sectioned into wafer-thin slices (typically a few microns in thickness) on a microtome. These slices are affixed to glass slides and stained so that they may be viewed under the microscope. The entire process may take several days, but must be completed before the pathologist can render a histologic diagnosis.

The College of American Pathologists (CAP) does allow for some specimens to be examined grossly without histopathologic examination. Which specimens may be handled in this manner is up to the discretion of individual departments (42). However, in most institutions foreign

bodies, tonsils, and adenoids fall under the "Gross evaluation only" umbrella. This is an important point to remember if tonsillectomy is being performed for diagnostic purposes as in the case of lymphoma or carcinoma. Again, if the requisition indicates a specific clinical concern rather than simply stating "Enlarged tonsil," the pathologist will be alerted and will perform the necessary steps for a more thorough analysis.

Reporting Standards

There are no specific guidelines for the reporting of benign disease. At a minimum, reports should include a definitive diagnosis and a statement regarding the status of the margins. Conversely, there are a number of organizations that issue publications related to the reporting of malignancy. For example, the World Health Organization periodically issues the Classification of Head and Neck Tumors as part of a series on classification of tumors from all sites (43). The American Joint Committee on Cancer (AJCC) and the International Union for Cancer Controls collaborate to maintain the staging systems used worldwide, with the AJCC leading these efforts in the United States (1). To help pathologists provide useful reports, the CAP publishes reporting guidelines for cancer (44). In fact, as part of the inspection process for accreditation, CAP reviews random reports to ensure they include the appropriate information.

HEAD AND NECK HISTOPATHOLOGY

The ability to recognize the histologic features of commonly encountered diseases and to understand the language of pathology reports are important skills for any surgeon to possess. Obviously surgeons cannot be expected to be expert diagnostic pathologists and a comprehensive review of head and neck histopathology is well beyond the scope of this chapter. Such an endeavor would itself require an entire textbook to be complete. Individual organ systems and diseases are discussed in the context of their associated pathologic findings elsewhere in this book. Consequently, the remainder of this chapter focuses on a few key concepts that will assist in interpreting pathology images and reports as they pertain to otolaryngologic diseases. To assist in this, we have also included an "atlas" containing a number of common epithelial neoplasms and their histopathologic description. All photos are stained with hematoxylin and eosin (H&E) unless otherwise noted (Figs. 12.1 to 12.25).

Special Stains

In reviewing pathology reports, one should pay attention to the stains used in slide preparation. Most commonly, this will be H&E. This mixture is universally employed for routine staining of tissues. Hematoxylin is a blue nuclear stain, while eosin is a pink counterstain that highlights cytoplasm as well as collagen. H&E staining allows specimens to be characterized morphologically. In many cases, a definitive diagnosis can be made based upon H&E alone. In others, however, the interpretation may not be so straightforward. Diseases may have overlapping microscopic features and may not be readily distinguished from one another. For instance, a benign paraganglioma can be morphologically similar to a medullary thyroid carcinoma on H&E staining. Despite their similar appearance, they have widely disparate clinical behaviors and treatments. Another more commonly encountered scenario involves diseases that are obviously malignant on H&E staining, but are too poorly differentiated to determine the cell of origin. For the pathologist to make a definitive diagnosis, additional testing is necessary. This testing is most often in the form of special stains.

A variety of special stains are available to aid the surgical pathologist. These take advantage of a cell's chemical makeup and may reveal features that are not otherwise discernable on H&E. They are most often used to highlight substances (mucin, amyloid, elastic), microorganisms (bacteria, fungi), or pigments and minerals (hemosiderin, iron, calcium). A list of histochemical stains that are frequently employed for head and neck specimens is provided in Table 12.1 (10).

IHC is another technique commonly used by surgical pathologists. IHC uses the principles of immunology to help determine the nature of a lesion (benign vs. malignant), prognosticate (HPV status), and establish site of origin. During this process, monoclonal antibodies directed at specific antigens are applied to the specimen. A second antibody is then bound to the targeted antibody. These are typically enzyme labeled (alkaline phosphatase, horseradish peroxidase) and produce a visible indicator in the presence of the antigen. The results are then qualitatively or semiquantitatively interpreted by the pathologist (10). Numerous commercially prepared antibodies are available and scores of these have relevance to otolaryngology.

A summary of commonly used IHC stains is provided in Table 12.2 (45).

SQUAMOUS CELL CARCINOMA AND ITS VARIANTS

A great deal of emphasis in otolaryngologic pathology centers around malignant diagnoses—the vast majority of which are SCC. Consequently, it is important that the otolaryngologist recognize some of the common features of SCC, its histologic variants, and its precursor lesions. In its native state, the surface of the upper aerodigestive tract is almost entirely covered by stratified squamous nonkeratinizing and respiratory epithelium.

(Text continued on page 194)

BENIGN NEOPLASMS

Salivary Gland Type Adenomas

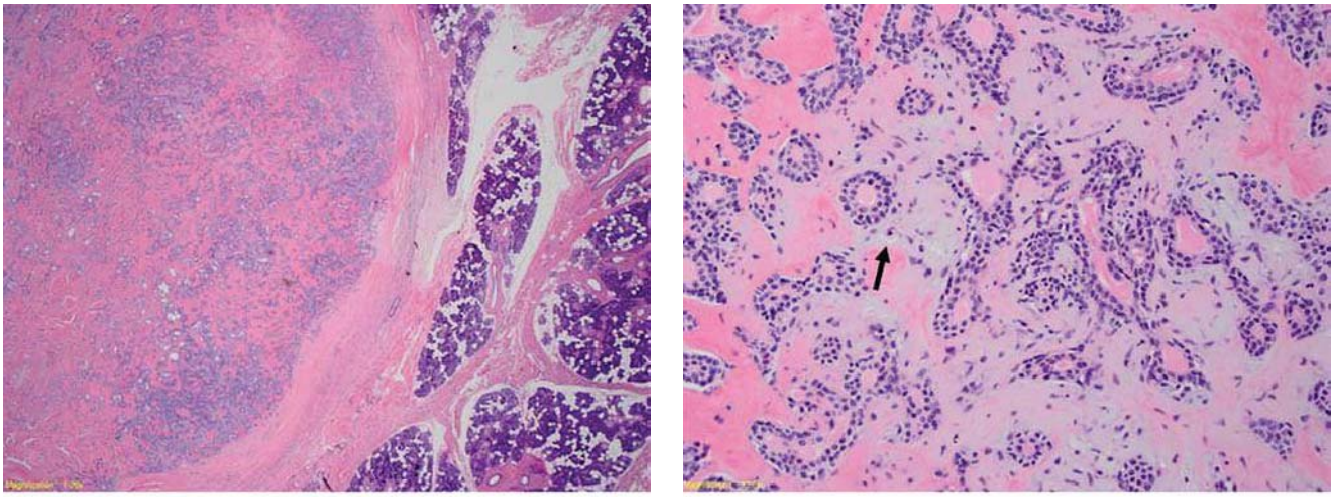

Figure 12.1 Pleomorphic adenoma. **A:** In the low-power photo (20×), the interface of the pleomorphic adenoma with the normal salivary gland may be seen (the latter is on the right hand side of this image). The lesion is encapsulated; this is one of the essential components of a pleomorphic adenoma. **B:** The intermediate-power photo on the right shows the other essential components: stromal elements, epithelia, and myoepithelial cells. At the center of this photo, mesenchymal cells with cartilaginous differentiation are evident (*arrow*). The duct-like structures show epithelial and myoepithelial cells (200×).

Sinonasal Papillomas

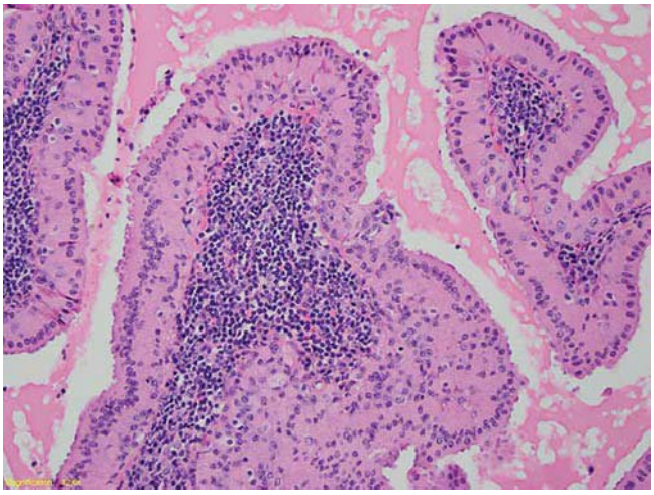

Figure 12.2 Warthin tumor (papillary cystadenoma lymphomatosum), with fibrovascular cores containing prominent lymphoid tissue. The epithelial lining is bilayered, with columnar oncocytic luminal cells and cuboidal basal cells. There are sometimes cystic areas that typically contain eosinophilic secretions (seen here); they may also contain crystals and laminated bodies (200×).

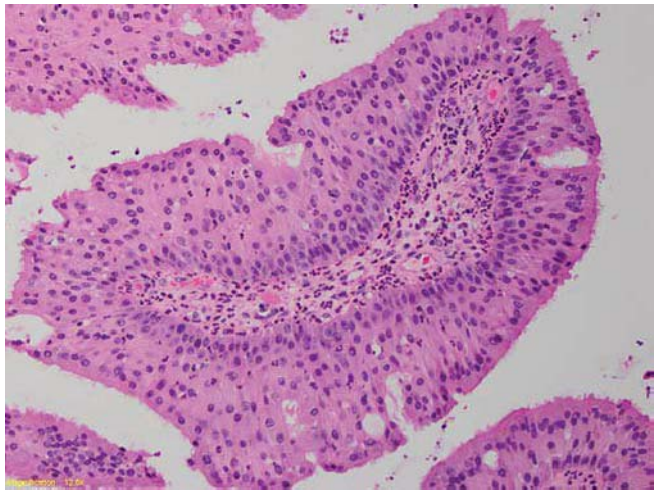

Figure 12.3 Exophytic Schneiderian papilloma, with a fibrovascular core covered by thickened respiratory and transitional epithelium and occasional clear mucus cells. Neutrophils are conspicuous (200×).

Squamous Precursor Lesions

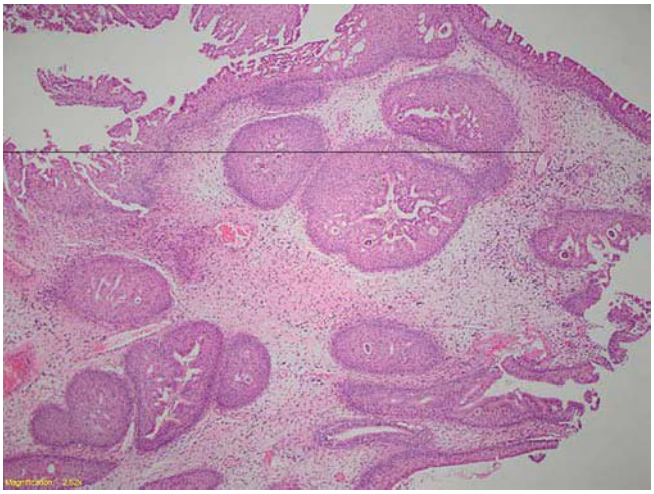

Figure 12.4 Inverted Schneiderian papilloma, with hyperplastic ribbons of transitional epithelium growing endophytically into the underlying stroma. The epithelium also contains occasional clear mucus cells (40×).

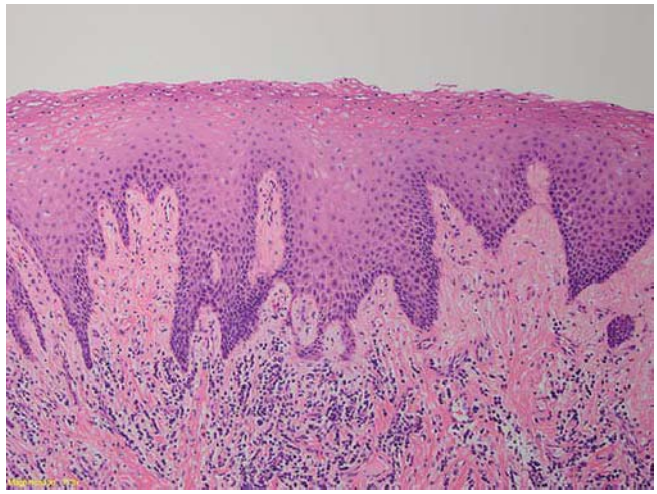

Figure 12.6 Squamous hyperplasia with increased epithelial thickness that remains orderly and without atypia (100×).

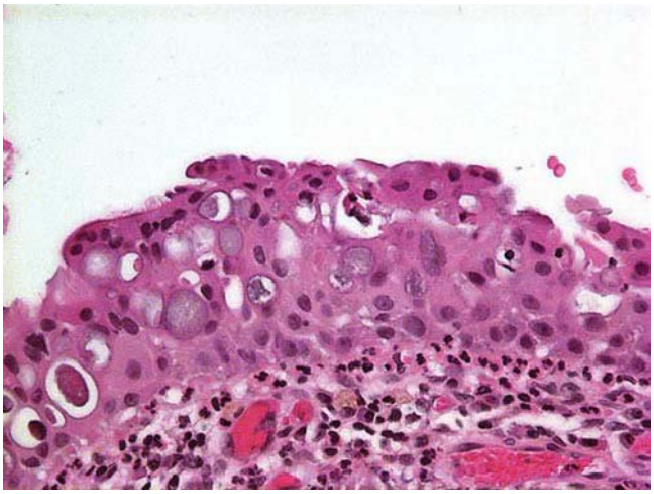

Figure 12.5 Oncocytic Schneiderian papilloma. The epithelium is composed of tall columnar cells with finely granular cytoplasm, reminiscent of oncocytes. Numerous microcysts and neutrophils are present (400×).

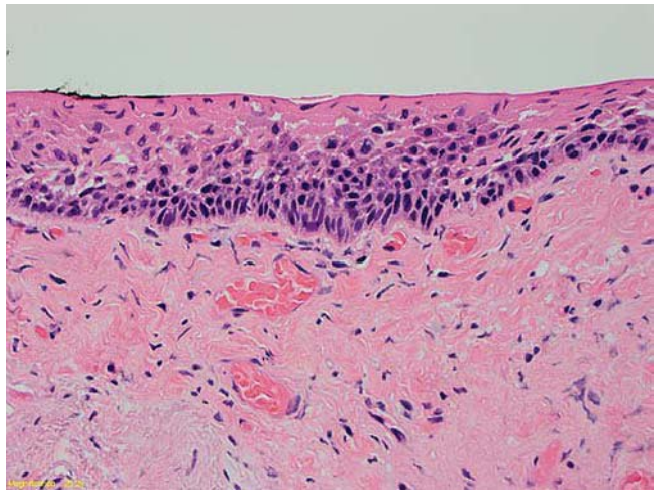

Figure 12.7 Mild squamous dysplasia. Architectural disorder (irregular stratification) with associated cytologic atypia (increased nuclear:cytoplasmic ratio, prominent nucleoli) confined to the lower third of the epithelium (400×).

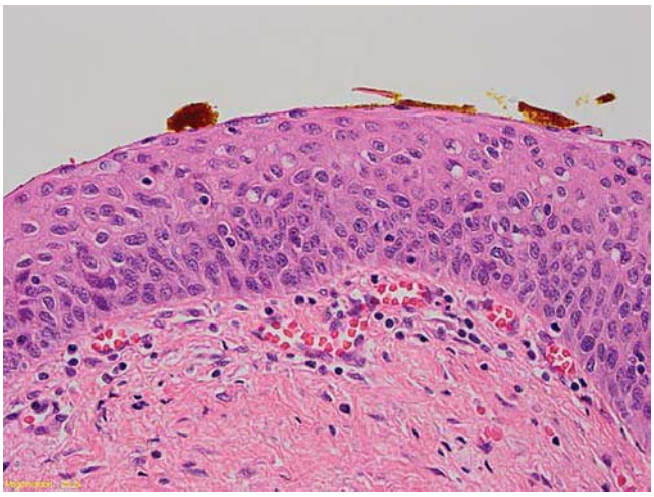

Figure 8 Moderate squamous dysplasia. Architectural disorder (irregular stratification) extending into the middle third of the epithelium with associated cytologic atypia (pleomorphism, increased N:C ratio, prominent nucleoli) (400×).

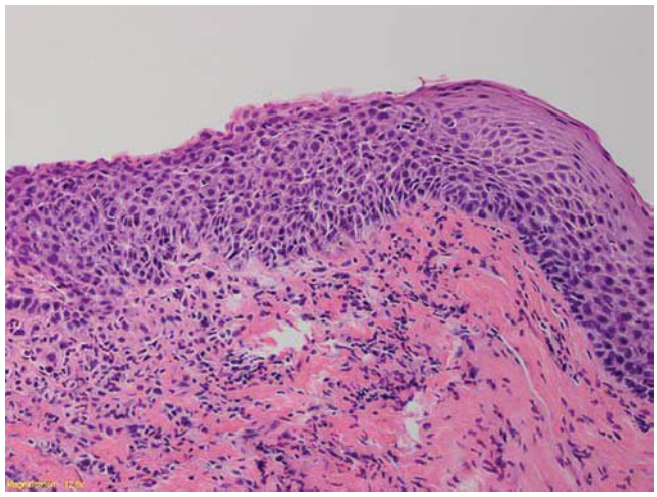

Figure 12.10 Severe squamous dysplasia on the left, with architectural irregularity and cytologic atypia extending to the top, with mild to moderate dysplasia on the right, where the irregularity and atypia is confined to the lower portions of the epithelium (200×).

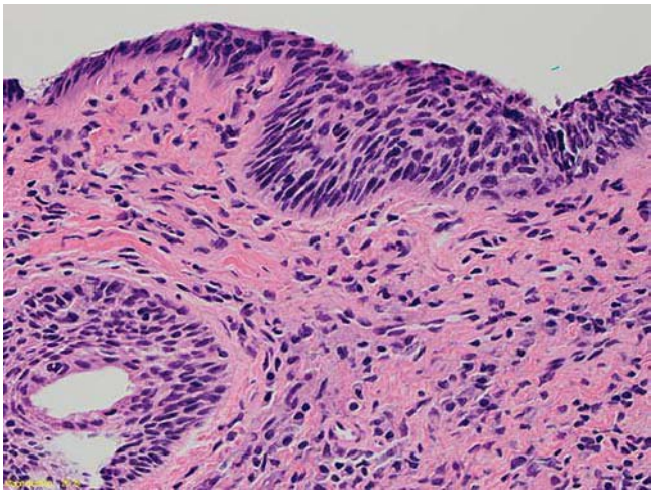

Figure 12.9 Severe squamous dysplasia. Architectural disorder (irregular stratification) extending into the upper third of the epithelium with associated cytologic atypia (pleomorphism, increased N:C ratio, prominent nucleoli). The specimen was previously frozen and shows resulting artifact. The dysplasia is also evident in a duct in the lower left of the photo (400×).

MALIGNANT NEOPLASMS

Squamous Cell Carcinoma and its Variants

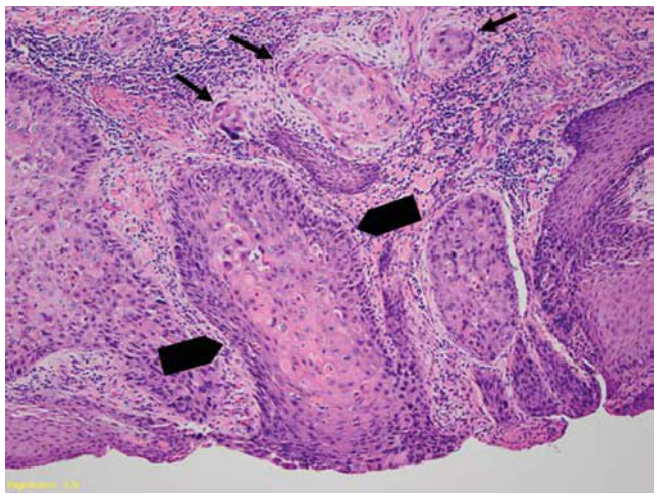

Figure 12.11 Invasive and *in situ* SCC. There is *in situ* carcinoma in the bottom middle of the photo (*arrowhead*). Deep to that (toward the top of the photo, *arrows*), are cohesive nests of large atypical cells with intercellular bridges, which incite a desmoplastic (or dense fibrotic) reaction, characteristic of invasive SCC (100×).

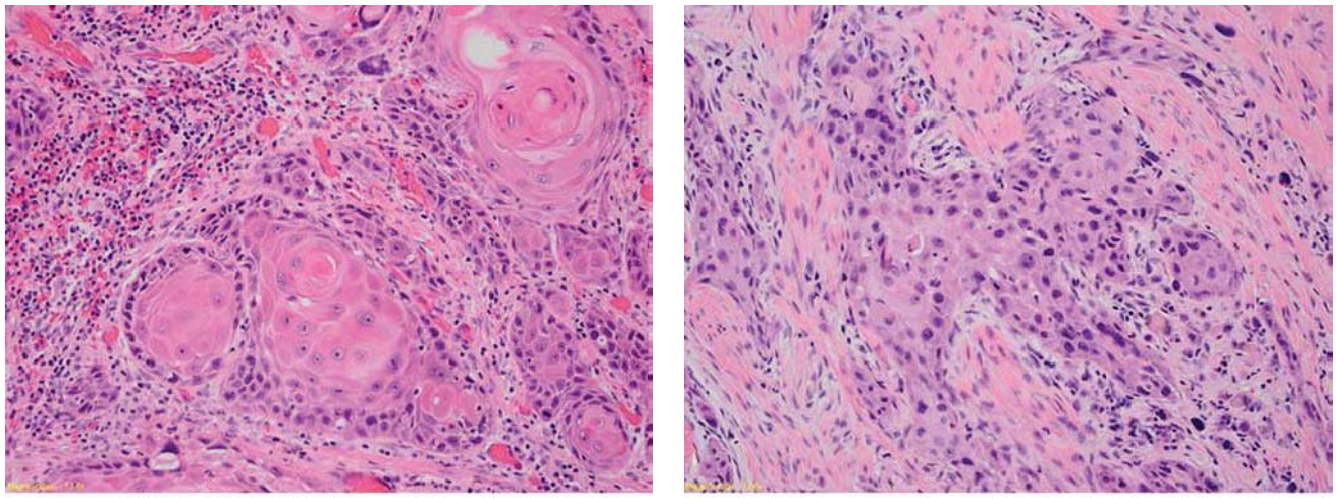

Figure 12.12 SCC, well (Panel A) and moderately differentiated (Panel B). **A:** The carcinoma in the photo is clearly invasive, but also displays obvious evidence of keratinization. **B:** The lesion demonstrated here is also invasive and has some evidence of keratinization (intercellular bridges and dyskeratotic cells), but to a lesser extent than is seen in the well-differentiated SCC (both images 200×).

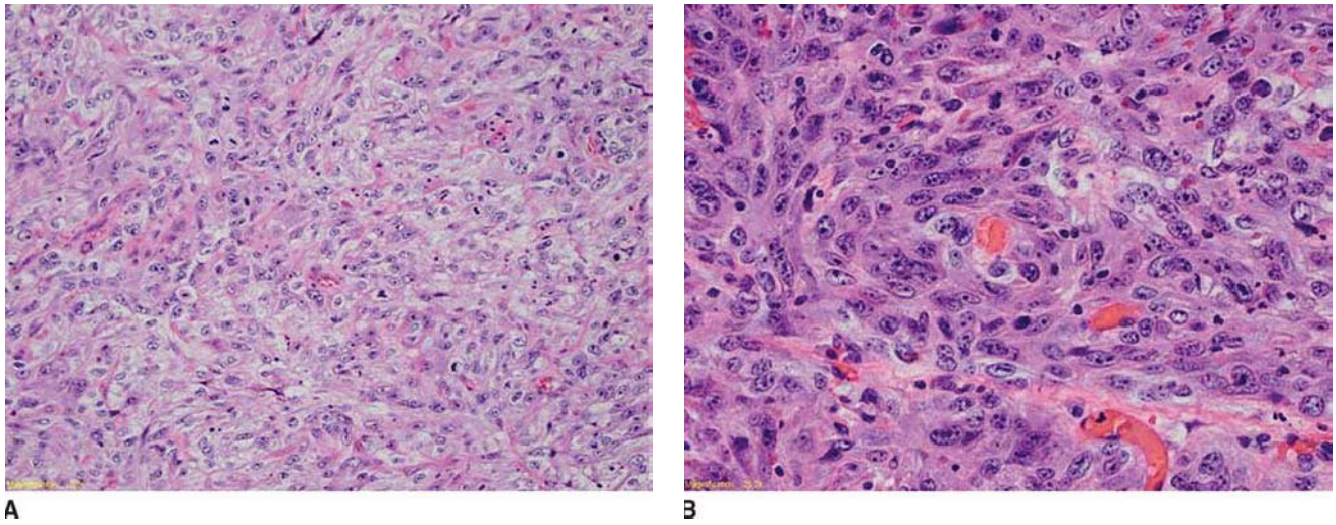

Figure 12.13 SCC, poorly differentiated. **A:** The photo depicts an obviously malignant neoplasm with little evidence of squamous differentiation (200×). **B:** The tumor seen here is also poorly differentiated, but with spindle cell features. This particular variant shows some residual evidence of squamous differentiation in the form of intercellular bridges. Some spindle cell carcinomas may be so poorly differentiated as to resemble sarcomas, requiring immunohistochemical or even electron microscopic evidence of epithelial differentiation for diagnosis (400×).

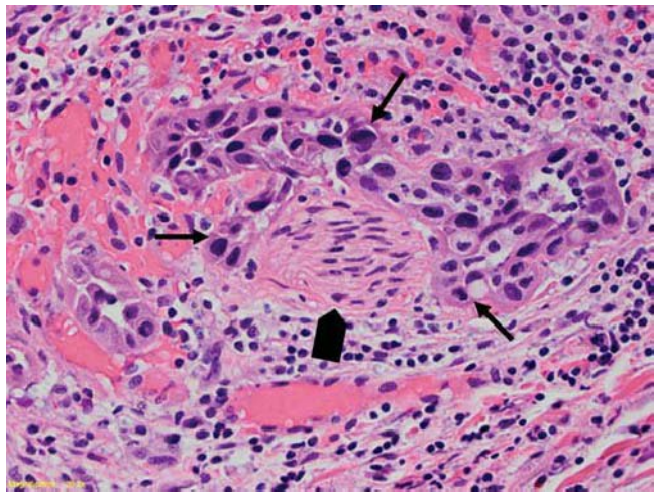

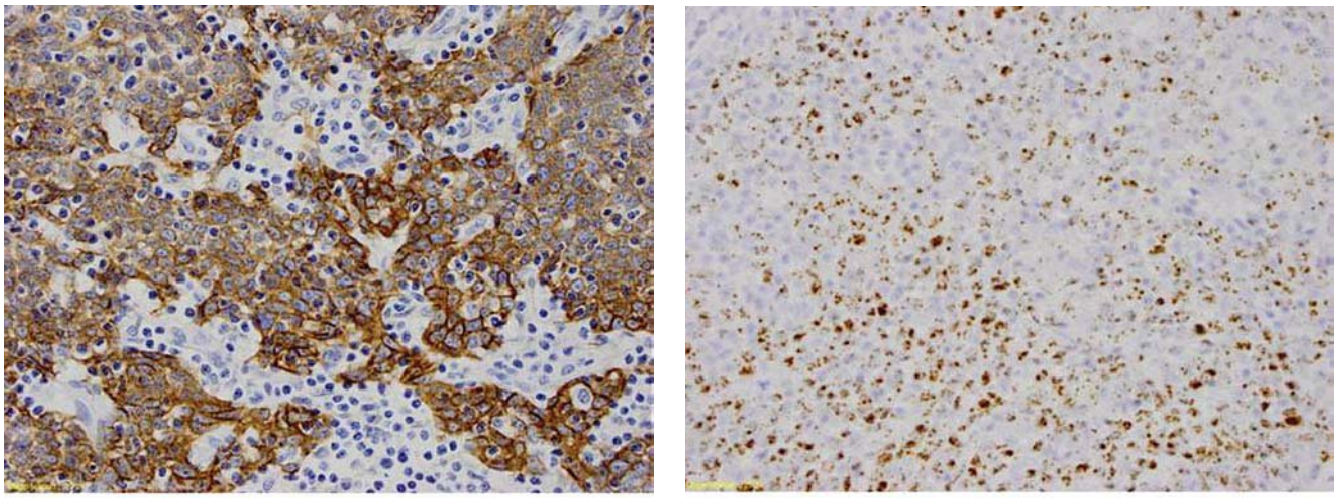

Figure 12.14 SCC with perineural invasion. The small structure in the center with wavy nuclei is a nerve (*arrowhead*). Malignant epithelial cells are evident immediately above the nerve (*arrows*). (400×).

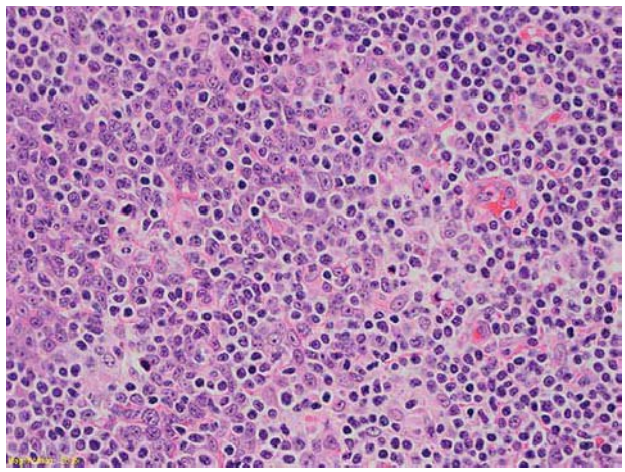
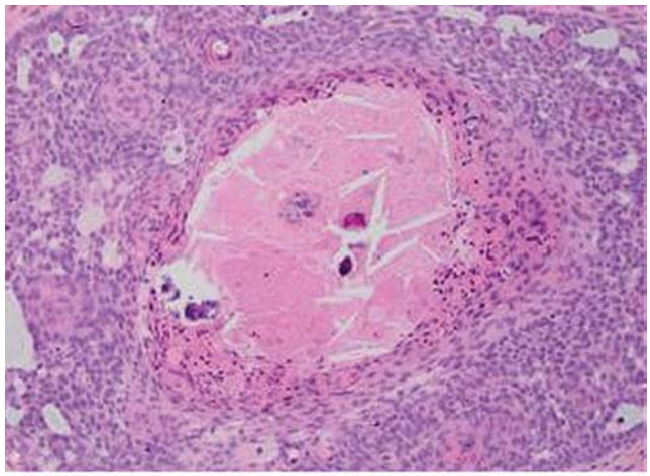
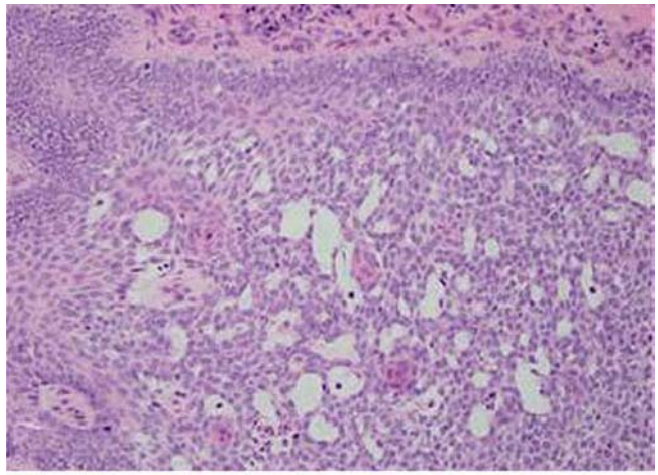
A B

Figure 12.15 **A:** IHC for epidermal growth factor receptor showing strong diffuse staining. **B:** ISH assay demonstrating HPV+ carcinoma (both photos 400×).







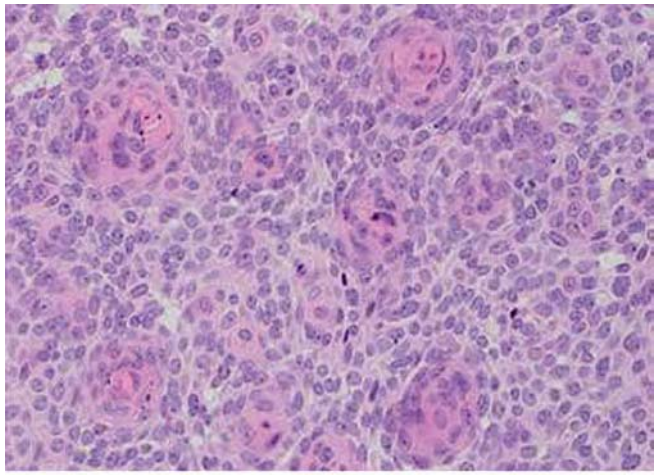


Figure 12.16 Lymphoepithelial carcinoma showing sheets of cells with indistinct cell borders imparting a syncytial appearance. Nuclei are vesicular with prominent nucleoli. Infiltrating lymphocytes are conspicuous (400×).

A

B

C

Figure 12.17 Basaloid SCC. **A:** Demonstrates the basaloid component, with small cells with scant cytoplasm and hyperchromatic nuclei, growing in solid sheets, with comedo-type necrosis. (200×). **B:** The cells exhibit peripheral palisading—the nuclei of the outer layer of cells are lined up perpendicular to the surface. Also evident in this photo are small cyst-like spaces. Both peripheral palisading and these cyst-like spaces are distinctive features of BSCC (200×). **C:** Foci of squamous differentiation within basaloid tumor island. BSCC have both basaloid and conventional SCC components (400×).

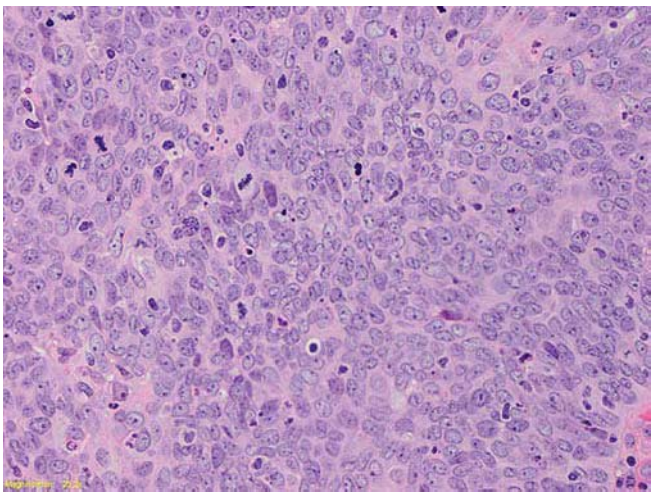

Figure 12.18 Nasopharyngeal carcinoma. The undifferentiated subtype pictured here shows large tumor cells growing in syncytial sheets. The cells are crowded and have oval vesicular nuclei with prominent nucleoli. The differentiated subtype, which is of no clinical significance and often coexists with the undifferentiated subtype, shows cells with well-defined borders and more (though still minimal) evidence of squamous differentiation. Numerous mitoses are present in this photo, as well as occasional lymphocytes (400×).

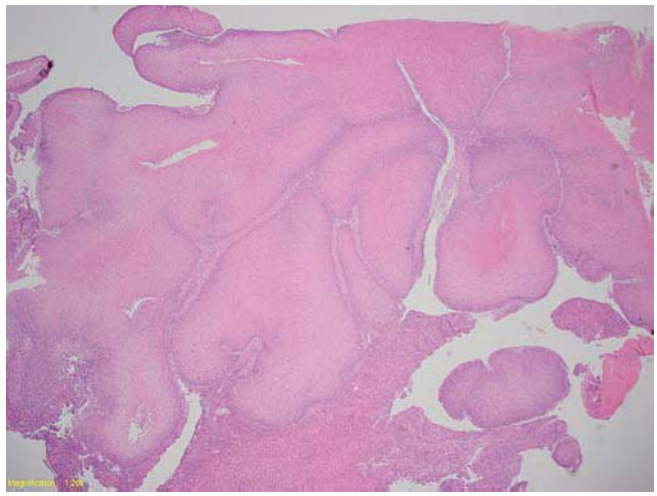

Figure 12.19 Verrucous carcinoma, low power showing well-differentiated epithelium without significant atypia invading into the stroma with pushing borders. The cells are typically larger than those seen in typical SCC (20×).

Salivary Gland-Type Carcinomas

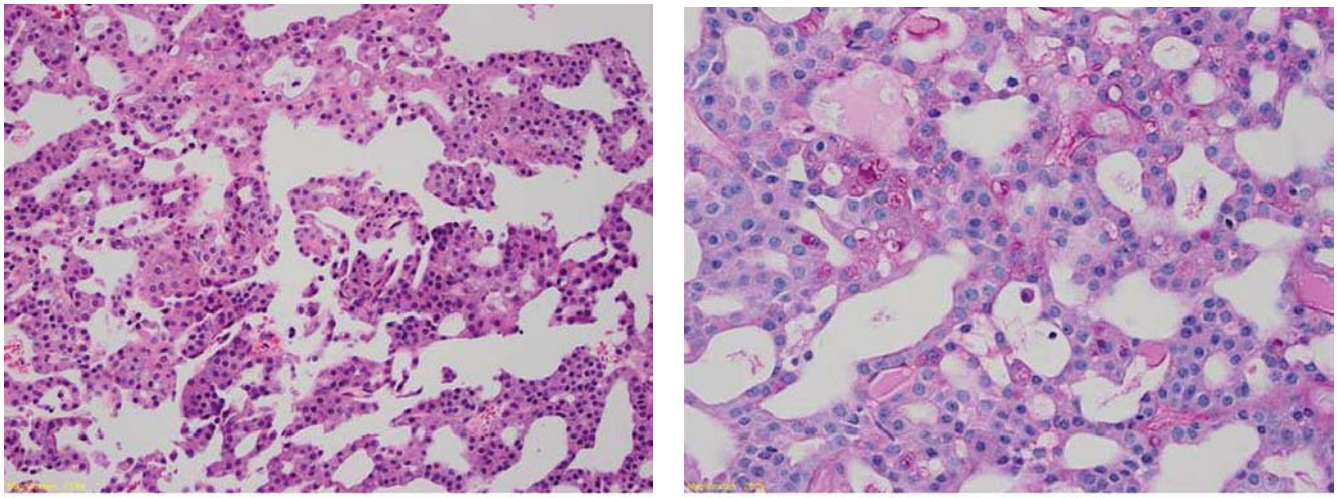

Figure 12.20 Acinic cell carcinoma. **A:** Demonstrates the typical polygonal cells with round eccentric nuclei, growing in sheets and lobules (200×). **B:** Periodic acid-Schiff (PAS)+ diastase resistant globules—another feature of acinic cell carcinoma (400×).

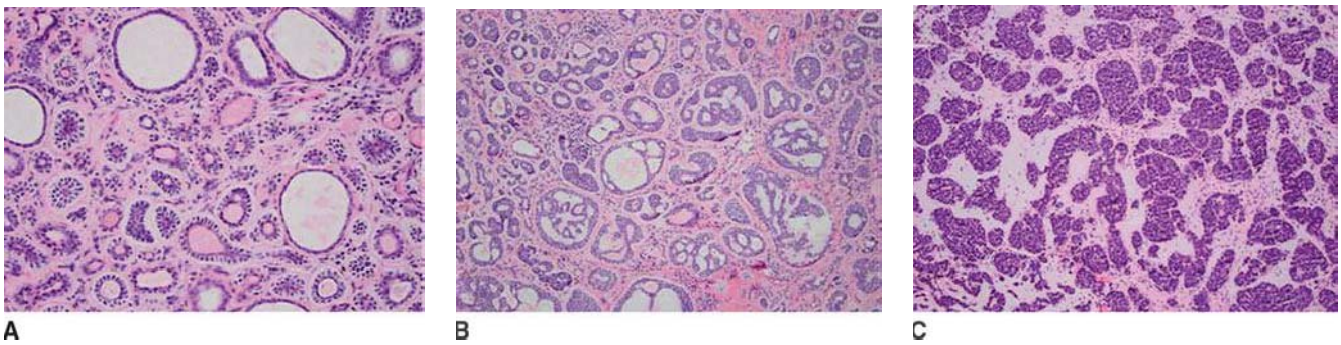

Figure 12.21 Adenoid cystic carcinoma. **A:** Well-formed ducts and tubules with central lumina, characteristic of the tubular pattern. (200×). **B:** Nests of cells containing microcystic spaces, characteristic of the cribriform pattern (100×). **C:** Sheets of uniform cells which lack tubules or cyst formation, characteristic of the solid pattern. (100×).

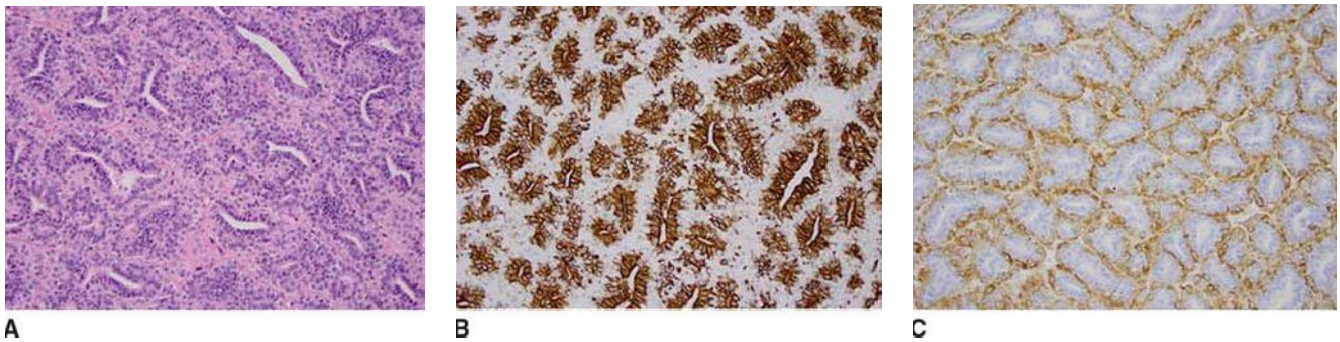

Figure 12.22 Epithelial–myoepithelial carcinoma. **A:** Duct-like structures with inner cuboidal cells with dense finely granular cytoplasm and outer polygonal cells with clear cytoplasm. **B:** Keratin IHC highlighting the inner layer of cells. **C:** Smooth muscle actin IHC highlighting the outer layer of cells (all photos 200×).

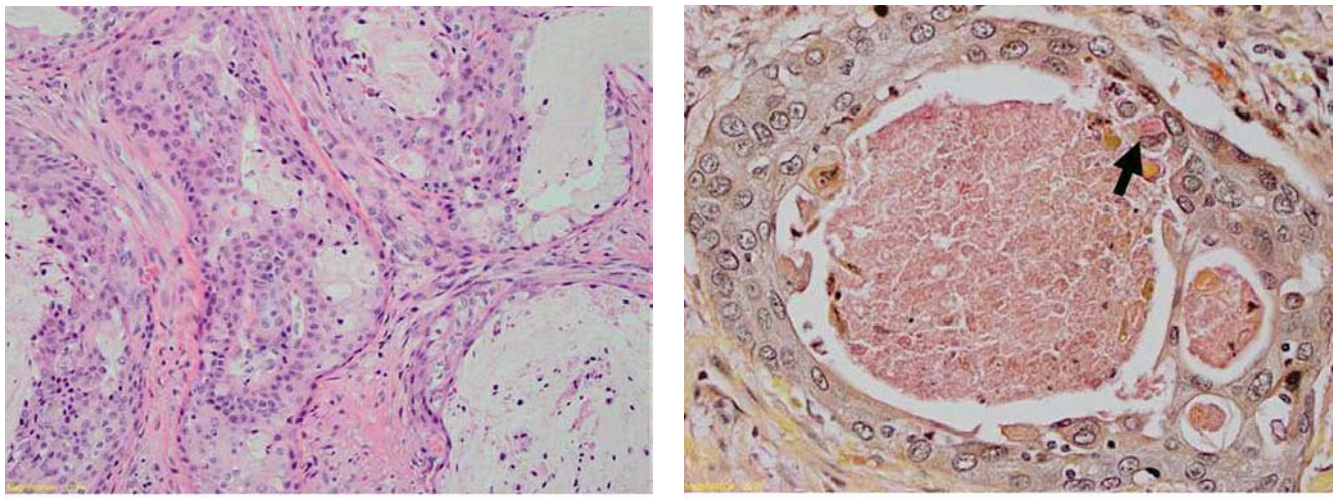

Figure 12.23 Mucoepidermoid carcinoma. **A:** Low grade, with squamoid (epidermoid) cells, mucus producing cells, and intermediate cells. The polygonal epidermoid cells and cuboidal intermediate cells predominate in this photo. Composition varies between tumors and even within a tumor (200×). **B:** High grade. There is necrosis in the middle of the photo, which is unusual in mucoepidermoid carcinoma. This mucin stain was performed to highlight rare mucus cells, one of which is evident at approximately 2 o'clock (*arrow*) (400×).

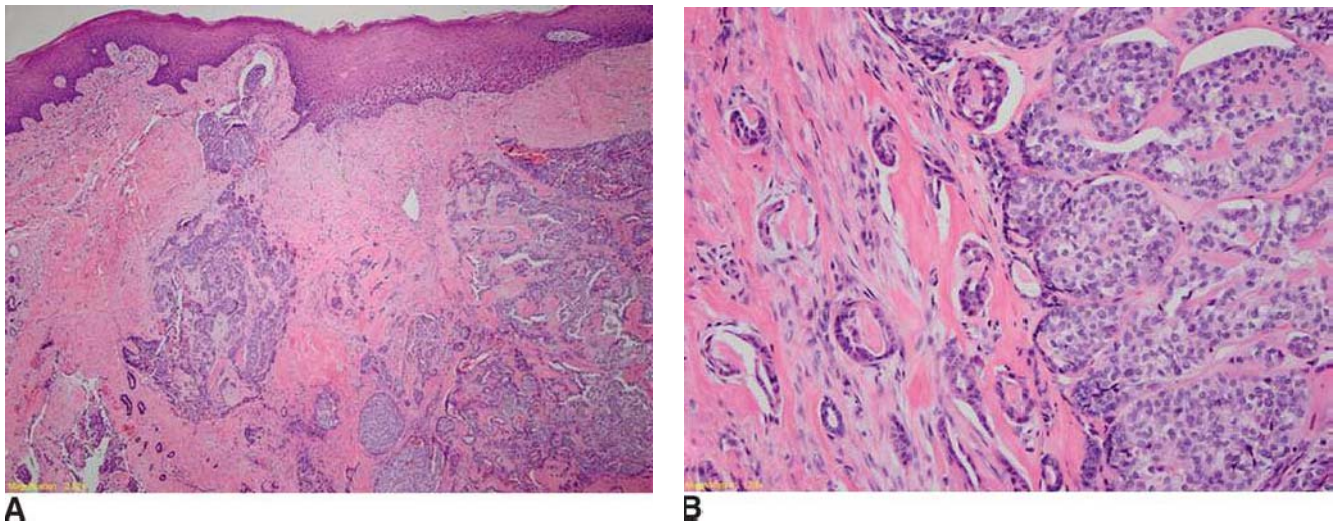

Figure 12.24 Polymorphous low-grade adenocarcinoma. **A:** Low power, showing infiltrative growth (40×). **B:** Demonstrates cytologic uniformity with small relatively bland cells. PLGA has morphologic variability: there are duct-like structures in panel A and more solid lobular growth in panel B. Other patterns include papillary and cribriform (200×).

Uncertain Histogenesis

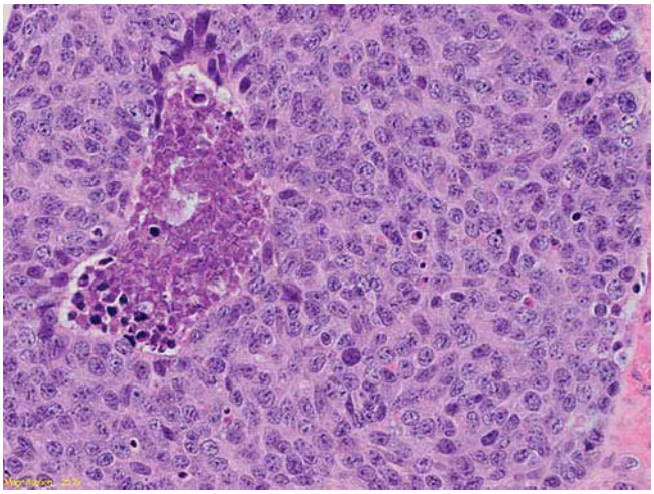

Figure 12.25 Sinonasal undifferentiated carcinoma, with sheets of medium-sized cells with scant cytoplasm. The nuclei have one or more prominent nucleoli. Tumor necrosis is evident, as are apoptotic cells (400×).

Dysplasia

Squamous mucosa is slowly but continuously replaced—with a gradual maturation of cells as they progress from the basement membrane to the surface. If this orderly transition is disrupted and less mature cells are present in the superficial layers of the mucosa, the tissue is said to be dysplastic. Dysplasia is defined as disordered growth with atypia (variations in size, shape, and nuclear appearance). The term is usually applied to changes within an epithelial lining. Dysplasia is by default a precancerous condition, though not all dysplastic lesions will progress to frank carcinoma. Dysplasia can represent a spectrum of changes between normal mucosa and invasive cancer. By convention, dysplasia is graded as mild, moderate, and severe. The risk of progression to malignancy does to some extent correlate with the grade of dysplasia, with the risk of severe dysplasia near 40% (46). Currently, there is no widely accepted grading system for head and neck dysplasia. As a result, significant inter- and intrarater variability exists (46–49). Despite the subjectivity, a general rule of thumb is that mild dysplasia occurs when there is minimal cytologic atypia confined to the lower third of the epithelium. Moderate dysplasia involves extension of the atypical changes into the middle third of the epithelium. In severe dysplasia, atypical changes extend into the top third of the epithelium and/or major cytologic atypia is present (48). When dysplasia involves the full thickness of the epithelium, it becomes known as a CIS. Invasive carcinoma is present when the basement membrane is breached by the disease.

Histologic Variants of Squamous Cell Carcinoma

Invasive SCC may be well, moderately, or poorly differentiated—depending upon the degree to which squamous cell morphology is maintained. It may be present as one of a variety of subtypes. Given the potential treatment and prognostic implications, three of these—spindle cell, basaloid, and verrucous carcinoma—merit particular attention.

Basaloid squamous (basosquamous) carcinoma is a high-grade variant of squamous carcinoma that is characterized by basaloid and squamous components. The basaloid cells tend to cluster at the periphery of the tumor while the squamous cell populations may be found near the center (50,51). Basosquamous carcinoma may involve any head and neck site, but it tends to be more common in the oropharynx, supraglottis, and hypopharynx. It is thought to be more aggressive than conventional SCC (46,50,52). However, a subset of these tumors are now believed to be related to the human papillomavirus (HPV) (51,53).

TABLE 12.1 HISTOCHEMICAL STAINS COMMONLY USED IN HEAD AND NECK PATHOLOGY

Histochemical Stain	Target	Otolaryngology Applications
Mucicarmine, Kreyberg, PAS	Intracellular mucin	Confirming adenocarcinoma:, Differentiating mucoepidermoid and squamous carcinoma
Gomori methenamine-silver	Fungal elements	Mucormycosis and actinomycosis
Acid-fast bacilli	Mycobacteria	Tuberculosis and atypical mycobacterial infections
Ziehl-Neelsen	Mycobacteria	Tuberculosis and atypical mycobacterial infections
Warthin-Starry Silver	Spirochetes, Bartonella	Syphilis Cat-scratch disease
Fontana-Masson	Melanin	Melanoma
Congo red	Amyloid	Amyloidosis

TABLE 12.2 IMMUNOHISTOCHEMICAL STAINS COMMONLY USED IN HEAD AND NECK PATHOLOGY

Stain Family	Specific Example	Positive	Examples/Uses
Keratins	Cam5.2; AE1-3; specific keratins (CK7, CK19 etc)	Epithelial cells	Carcinoma; Can sometimes be used to help determine site of origin (ex: colon cancer is CK7−/CK20+; breast Cancer is CK7+/CK20−)
Squamous	p63; CK5/6	Squamous cells	Confirm squamous differentiation in poorly differentiated carcinomas.
S-100	S-100	Neural crest derivatives; chondroid, fat and myoepithelial cells	Melanoma; schwannoma
HMB-45	HMB-45	Immature melanosomes	More specific than S-100 for melanoma; Also positive in angiolipoma, tuberous sclerosis and rarely carcinomas
Lymphoid markers	LCA (CD45); CD3; CD5; CD20; CD79a	White cells (LCA); T cells (CD3, CD5); B cells (CD20, CD79a)	Lymphoma
Actins	SMA; MSA	Smooth muscle/myoepithelial cells	Leiomyoma (SMA); rhabdomyosarcoma(MSA)
Vascular	FVIII, CD31	Endothelial cells, megakaryocytes, platelets	Hemangioma; hemangioendothelioma; confirmation of vascular invasion
Neuro-endocrine	NSE, chromogranin, synaptophysin, CD56	Neuroendocrine cells	Paragangliomas, carcinoid, small cell carcinoma
Neural	GFAP; CD57 (Leu-7)	Intermediate filaments (GFAP) and glycoproteins (CD57) of Schwann cells	Differentiate schwannoma from other spindle neoplasms
Cell proliferation Marker	Ki-67	Cells not in G0	Burkitt lymphoma
Tissue specific	TTF-1; thyroglobulin Calcitonin; Melan-A	Lung and thyroid (TTF-1); Thyroid Follicular Epithelium (thyroglobulin); Thyroid C-cells (Calcitonin); MART-1 antigen (Melan-A)	Confirm a primary thyroid or lung carcinoma. Confirm presence of medullary thyroid carcinoma. Confirm the diagnosis of melanoma (Melan-A)

Despite identical morphology, HPV positivity is indicative of a highly significant survival advantage when compared to HPV-negative basaloid squamous carcinoma (51).

Histologically, the spindle cell variant (sometimes referred to as carcinosarcoma) is a cytologically malignant proliferation of fusiform cells that are intimately associated with obvious elements of SCC. Confirmation of a squamous cell origin is typically made immunohistochemically. Spindle cell tumors are most often seen in the larynx—with the true vocal folds involved more often than the supraglottis (46). Though the body of literature pertaining to these tumors is somewhat limited, they are widely thought to be more aggressive than conventional SCC (46,52). Given the apparent negative prognostic implications, aggressive multimodal therapy is typically recommended.

Verrucous carcinomas, on the other hand, are low-grade malignancies. They are commonly identified in elderly patients and are named for their verrucous, or wart-like, appearance—both grossly and histologically. Given its appearance, a viral etiology has been proposed, though no definitive evidence has been uncovered to date. On light microscopy, these tumors appear as uniform groups of cells without significant dysplastic features. They demonstrate marked surface keratinization and broad pushing borders without evidence of infiltration (46). These lesions have a relatively indolent course, but can be locally destructive if left unattended. They are readily treated with surgical excision. Their principal import rests in the fact that verrucous carcinoma has long been considered to be a contraindication to radiotherapy. Early reports indicated that these tumors were not sufficiently radiosensitive and that they were prone to anaplastic transformation after definitive radiation therapy. Subsequent studies of larger and more controlled patient populations have failed to demonstrate any cases of anaplastic transformation. These studies did confirm that local control rates for verrucous carcinoma are better with surgery than with radiation. The ultimate local control and survival statistics after surgical salvage are comparable, however (54). In essence, the evidence seems to indicate that while this disease is most appropriately treated with surgery, it should not be considered a contraindication to radiotherapy.

Adverse Pathologic Features in Squamous Cell Carcinoma

Given the potential therapeutic implications, reporting of SCC should not only include a description of tumor grade and subtype but also a description of histologic features of known prognostic significance. We have already discussed resection margins and their significance in detail. However, the presence or absence of a number of other findings must be noted by the pathologist if a report is to be considered complete. Primary tumors should be evaluated for perineural and lymphovascular invasion. It has been repeatedly demonstrated that perineural spread is an independent risk factor for locoregional recurrence and mortality (55,56). This holds true even for minor (less than 1-mm diameter) nerve involvement. It is therefore imperative that the pathologist pay careful attention to this feature and make the appropriate comments in his or her report. Though somewhat less pronounced than perineural invasion, lymphovascular invasion also has deleterious effects upon locoregional control and survival (56). The depth of tumor invasion also appears to bear prognostic significance in oral cavity cancers. Depth of invasion has been correlated to an increased risk for occult nodal disease in early-stage tongue and floor-of-mouth cancer (57,58). A 2009 meta-analysis confirmed this and concluded that early-stage tumors greater than 4-mm-thick require elective treatment of the neck (59).

In recognizing the importance of perineural spread, lymphovascular invasion, and tumor thickness, CAP now recommends that they be included in all reports. Unfortunately, as evidenced in a recent study by Goodman and colleagues, a majority of pathologists still do not comment on depth of invasion or mode of spread (56). Reporting of this information should be the rule rather than the exception. If these features are not described, it is appropriate to ask the pathologist to review the case and issue an addendum. It is also an opportunity to request that all reports be updated to reflect CAP standards.

Identification of Human Papillomavirus–Related Squamous Cell Carcinoma

HPV-related oropharyngeal cancers are increasing in incidence at an alarming rate (60). Despite the fact that they are squamous carcinomas, HPV-related cancers are clinicopathologically unique from conventional SCC. Patients with HPV-related SCC are typically younger, they have distinct risk factor profiles, and their prognosis is improved when compared to cohorts with HPV-negative tumors (61–63). The prognostic advantages of HPV-related SCC are limited to oropharyngeal tumors and have not been consistently demonstrated for other subsites (64). The biology and clinical behavior of these tumors are described in detail elsewhere in this text. HPV now accounts for the largest percentage of new head and neck cancers in the United States and it is important to discuss some of the pathologic features that assist in making the diagnosis of an HPV-related SCC.

HPV is a DNA virus that preferentially infects basal epithelia. Several high-risk subtypes have been identified, but HPV16 is the most frequently implicated in head and neck cancers (63). In the oropharynx, it most likely gains entry via the specialized epithelium located at the base of tonsillar crypts (65). Once inside the cell, the viral DNA integrates with the host and encodes a number of proteins. Tumorigenesis is largely dependent upon the production of the E6 and E7 viral proteins. These structures are capable of inactivating the tumor suppressors p53 and pRB and, consequently, promoting unchecked cell growth (66).

While many HPV-related tumors may appear similar to conventional SCC on light microscopy, the evidence suggests that these are more likely to be poorly differentiated or basaloid in nature (61,65,67). Poorly differentiated and basaloid SCC are also observed in HPV-negative cancers, and the presence of these variants are not sufficient to establish HPV as a cause. As noted above, when there is overlap of light microscopic features, special stains and tests are often necessary to confirm a tumor's origin, or, in this case, its etiology and prognosis. A number of assays for the detection of HPV are now commercially available. The gold standard remains polymerase chain reaction (PCR). PCR is highly sensitive and specific and can detect a single copy of viral DNA. This technique is of limited clinical utility due to its high cost and the lack of widespread availability (68). Alternative methods include *in situ* hybridization (ISH) for HPV DNA and immunohistochemical staining for p16, a protein that is upregulated by viral E6 and is widely considered to be a surrogate for the presence of HPV infection. Both methods are widely available, relatively inexpensive, and easily interpreted. p16 is highly sensitive for the detection of HPV, but lacks specificity. HPV ISH, on the other hand, is a very specific test that lacks sensitivity (63,65,68,69). Using the area under receiver operating curves as a measure of overall test performance, Schlect et al. (69) found that p16 IHC was superior to ISH in confirming the presence of HPV in SCC. Interestingly, the authors also found that p16 staining intensity was inversely correlated to the degree of keratinization on light microscopy. Knowledge of an oropharyngeal cancer patient's HPV status carries with it tremendous prognostic and counseling implications. Ultimately, it may also affect management decisions. It is thus advocated that all oropharyngeal carcinomas be screened using one of the above-mentioned methods—with preference given to p16 IHC if it is available.

HIGHLIGHTS

- Communication between the otolaryngologist and pathologist is of paramount importance.
- Preferred biopsy techniques of epithelial lesions include incisional, excisional, and punch. Shave biopsies should be avoided, especially in pigmented lesions.
- FNA is a safe, well-tolerated, useful technique of sampling thyroid and salivary gland nodules, as well as enlarged lymph nodes. Its accuracy and diagnostic yield may be improved using image guidance.
- Margin assessment is most accurate when there is a well-orchestrated handoff between the surgeon and the pathology team. Surgeon-directed specimen orientation and inking are critical to this process.
- Intraoperative frozen section provides accurate information, but its use should be restricted to situations where the results will change operative management.
- Reporting of head and neck malignancies should be standardized, with explicit attention to the tumor subtype and the presence or absence of adverse pathologic features.

Neurology in Otolaryngology

13

Rachel E. Roditi *Benjamin T. Crane*

Many neurologic disorders present with symptoms in the head and neck region. Thus, it is important for the general otolaryngologist to recognize these neurologic disorders in order to initiate management or arrange for proper and prompt referral to the appropriate physician. Further, since otolaryngologists are most familiar with head and neck anatomy and physiology, they may play an active role in the multidisciplinary care of patients with primary neurologic disorders. Thorough understanding of the cranial nerves, neurologic examination, and the neurologic diseases frequently presenting with head and neck symptomatology is of utmost importance. A screening neurologic examination is helpful in detection of neurologic diagnoses affecting the head and neck. This provides a quick method for evaluating mental status, cranial nerves, the motor system, gait, balance and coordination, reflexes, and sensation. This chapter addresses many of the most common and important issues in neurology for the otolaryngologist to understand.

ANATOMY AND CRANIAL NERVE FUNCTIONS

When neurologic diseases involve the head and neck region, cranial nerve deficits are important to recognize. Understanding of cranial nerve anatomy and function, as well as the ability to perform a proper cranial nerve examination is key (Figs. 13.1 and 13.2). Table 13.1 outlines the cranial nerves and examination findings.

CEREBROVASCULAR DISEASE

Abnormalities of blood flow to the central nervous system (CNS) are a common cause of morbidity and mortality across the world. In the United States, cerebrovascular disease is the third leading cause of death and the primary cause of long-term disability (1). Stroke can be either hemorrhagic or ischemic in nature, with ischemic strokes being far more common and making up approximately 87% of all cerebrovascular events (1). Clinical presentations and functional deficits can be quite variable depending on the area of the CNS involved. Permanent losses typically result from complete arterial occlusion or from hemorrhagic infarction. Transient effects may accompany arterial stenosis, vascular spasm, inadequate perfusion pressure, or reversed arterial flow with shunting such as subclavian steal syndrome.

The blood supply to the inner ear, brainstem, and cerebellum arises from the vertebrobasilar system, thus vertigo is a common manifestation of cerebrovascular disease and can be caused by occlusion of any of the three major circumferential branches of the vertebral or basilar arteries: the posterior inferior cerebellar artery (PICA), the anterior inferior cerebellar artery (AICA), and the superior cerebellar artery (SCA) (Fig. 13.3).

Vertebrobasilar Insufficiency

Vertebrobasilar insufficiency is a significant cause of vertigo in individuals over age 65 (2). Vertigo due to vertebrobasilar insufficiency has a sudden onset, usually lasts several minutes, and is often associated with nausea and vomiting. Because of the presence of vertigo symptoms, the otolaryngologist may be called upon to make this diagnosis; however, vertigo symptoms alone are extremely uncommon and occur in less than 1% of patients (3). Usually, multiple symptoms suggestive of central etiology are present which often include headache, diplopia, ataxia, numbness, weakness, or oropharyngeal dysfunction (4). Repeated episodes of vertigo without other symptoms suggest another diagnosis.

Atherosclerosis of the subclavian, vertebral, or basilar arteries is often the underlying cause of vertebrobasilar insufficiency. The distribution of atherosclerosis differs according to race and gender (5). European men tend to have

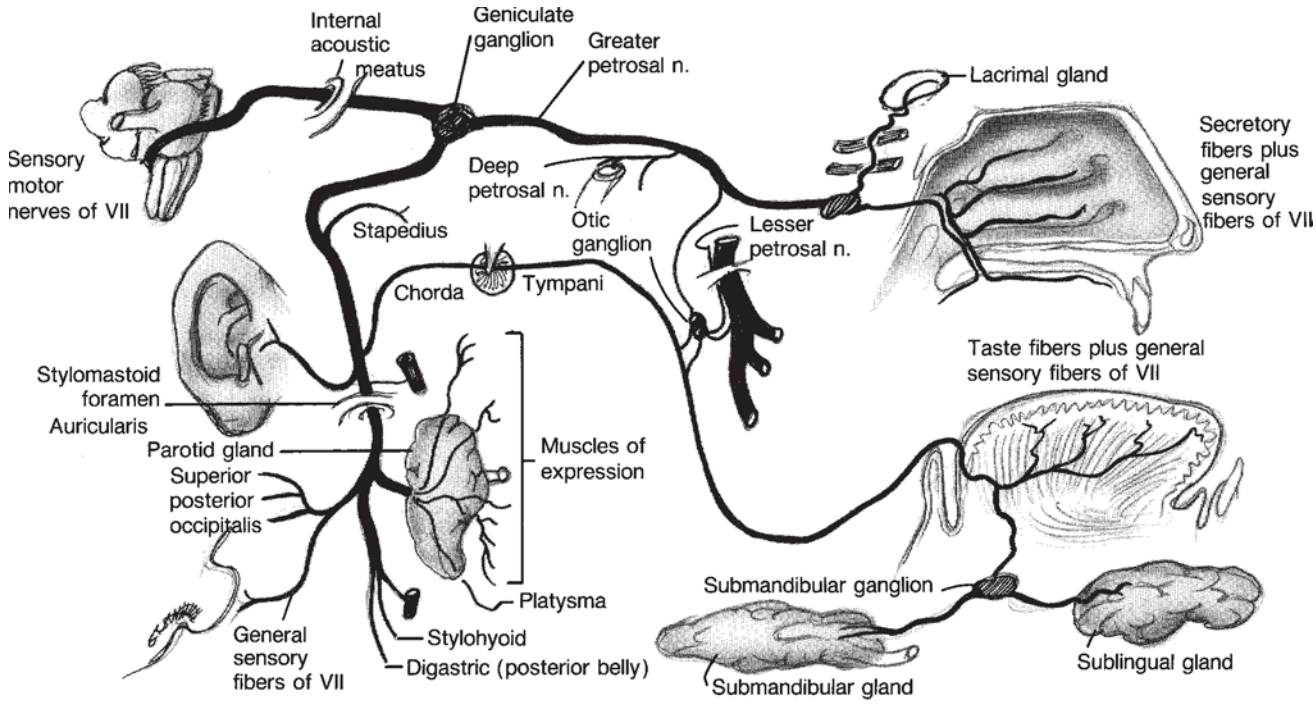

Figure 13.1 Facial nerve.

atherosclerosis at the origin of the vertebral arteries near the subclavian. Intercranial large-artery atherosclerosis is more common among African Americans, Asians, and women. Hypertension increases the risk of lipohyalinotic thickening of these vessels, which increases the risk of infarction.

If a patient is suspected to have had a stroke, a computed tomography (CT) scan without IV contrast should be ordered to rule out the possibility of a hemorrhagic event. Patients with ischemic strokes who present within three hours of the onset of symptoms should be considered for administration of intravenous tissue-type plasminogen activator (6). However, recommendations in this area are rapidly evolving, and a neurologist familiar with stroke should treat acute patients.

In most patients with nonacute presentation, treatment consists of controlling risk factors such as diabetes, hypertension, and hyperlipidemia. In patients with symptomatic intracranial stenosis of 50% to 99%, aspirin is the treatment of choice. Anticoagulation with warfarin should be considered if the patient has previously had an embolic stroke, which is cardiac in origin (2). Stenting of vertebral artery stenosis has been attempted with mixed results. Endarterectomy for extracranial vertebral artery disease has also been successfully performed, but indications for such procedures are still evolving.

Lateral Medullary Syndrome

Lateral medullary syndrome (Wallenberg syndrome) is caused by an infarction involving a wedge of the dorsolateral medulla just posterior to the olive (Fig. 13.4). The syndrome usually results from occlusion of the ipsilateral vertebral artery and rarely from occlusion of the PICA (7). Classic presentation includes sensory deficits affecting the trunk and extremities on the opposite side of the infarct and sensory and motor deficits affecting the face and cranial nerves ipsilateral to the infarct. Characteristic symptoms include vertigo, ipsilateral facial pain, diplopia, dysphagia, and dysphonia. Neurologic examination may reveal an ipsilateral Horner syndrome, ipsilateral dysmetria, dysrhythmia, spontaneous nystagmus, and contralateral loss of pain and temperature sensation. Hearing is not preserved because the lesion is caudal to the cochlear nerve entry zone and cochlear nuclei.

Lateral Pontomedullary Syndrome

Occlusion of the AICA results in infarction of the dorsolateral pontomedullary region and the inferolateral cerebellum (8). The middle cerebellar peduncle is typically the core of the affected territory (Fig. 13.5). Because the labyrinthine artery originates from the AICA in 80% of patients, infarction of the membranous labyrinth is a common accompaniment. Severe vertigo, nausea, and vomiting are common initial symptoms. Other symptoms include ipsilateral hearing loss, tinnitus, facial paralysis, and cerebellar asynergy. Spontaneous nystagmus is common. Contralateral loss of pain and temperature sensation may be caused by crossed spinothalamic fibers. Onset of symptoms is acute followed by gradual improvement. Vertigo may persist longer than would be expected from a pure vestibular lesion due to damage of the central compensation mechanisms.

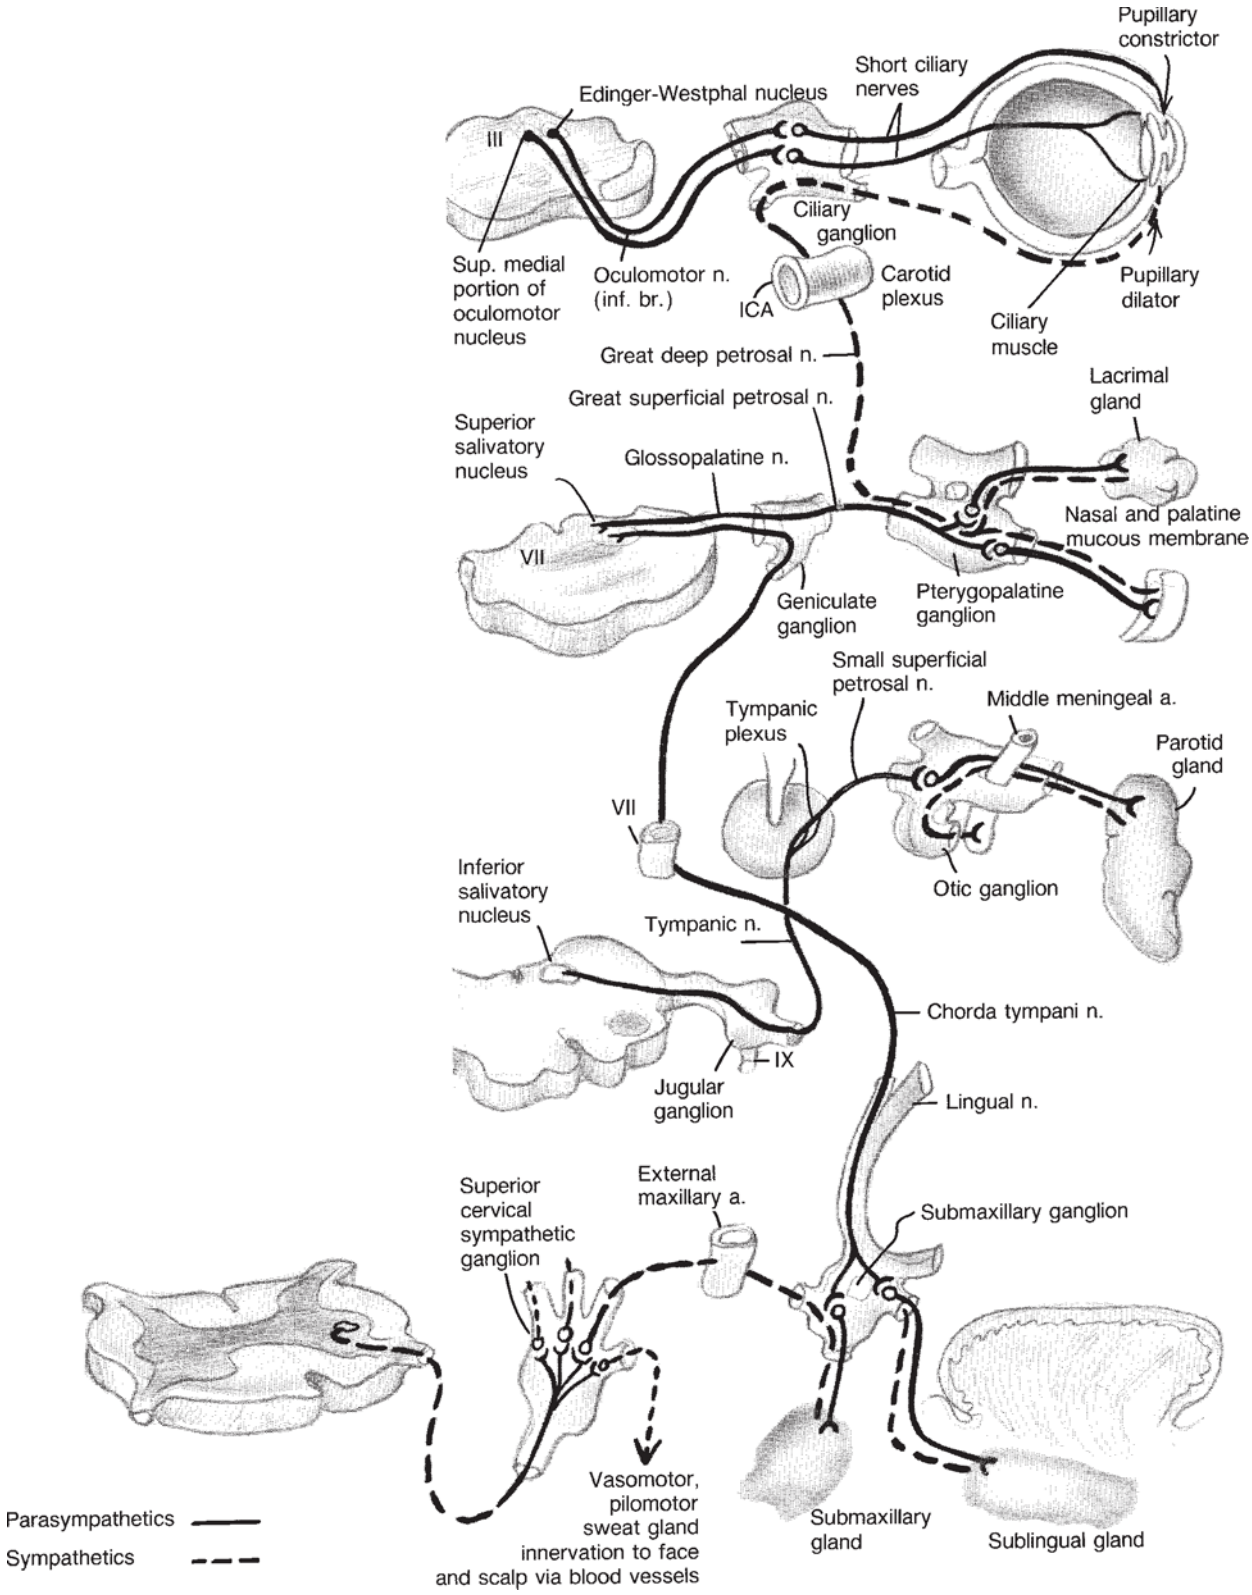

Figure 13.2 Cranial nerve autonomic ganglia. The parasympathetic nervous system (*solid lines*) has ganglia close to the structure being innervated. The sympathetic nervous system (*dashed lines*) originates from three cervical ganglia. The superior cervical ganglion communicates with cranial nerves IX, X, and XII supplying the pharyngeal plexus, carotid sinus, and carotid body. The middle cervical ganglion is often small or absent. The inferior cervical ganglion is often fused with the first thoracic ganglion to form the stellate ganglion to provide sympathetic input to the upper limb.

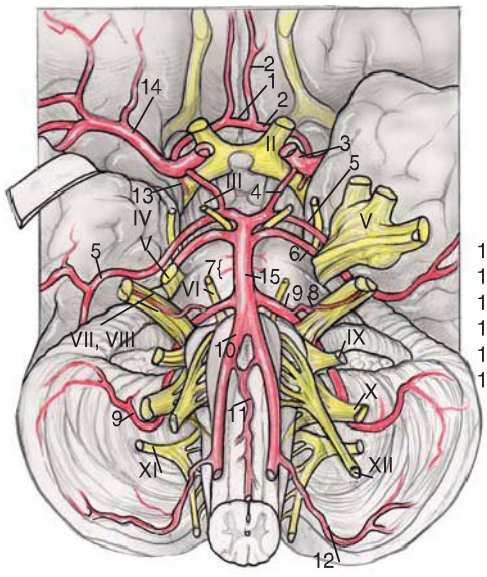
TABLE 13.1 CRANIAL NERVES AND RELATED CLINICAL FINDINGS

Cranial Nerve	Clinical Relevance	Typical Lesion	Abnormal Findings
I	Smell	Fracture of cribriform	Anosmia, CSF leak.
II	Vision	Fracture involving optic canal	Visual field defect
III	Ocular motility	Cavernous sinus thrombosis	Dilated pupil, ptosis, eye turns down and out
IV	Superior oblique innervation	Damaged cutting of the tentorium during middle fossa approach to large tumor	Inability to look down and in
V	Facial Sensation Motor to muscles of mastication (V3)	Pressure on trigeminal ganglion from intracranial tumor	Loss of pain and touch sensation. Deviation of mandible to the side of the lesion when it is opened.
VI	Abduction of the eye	Cavernous sinus thrombosis	Diplopia, failure of eye to move laterally
VII	Facial motion Taste sensation to anterior 2/3 of the tongue.	Facial laceration Bell palsy Fracture of temporal bone	Paralysis of facial muscles As above + loss of taste
VIII	Hearing and Balance	Vestibular schwannoma	Unilateral hearing loss, tinnitus, loss of balance function
IX	Taste to posterior tongue, palate elevation	Brain stem lesion	Loss of taste, palate sensation, and elevation.
X	Parasympathetics, Vocal cord mobility	Injury during thyroidectomy	Hoarse voice, aspiration, vocal cord paralysis
XI	Lifting of the shoulder	Injury during neck dissection	Paralysis of trapezius, poor shoulder elevation
XII	Protrusion of the tongue	Tumor involving floor of mouth	Tongue deviates toward the side of the lesion, dysarthria.

Midbrain Syndromes

Occlusion of the posterior cerebral artery (PCA) or its more distant branches can result in several brainstem syndromes that may present with cranial neuropathies (Fig. 13.6). *Paramedian midbrain syndrome (Benedikt syndrome)* involves the oculomotor fascicle, red nucleus, medial lemniscus, and dentatothalamic tract. An ipsilateral oculomotor nerve paresis with contralateral chorea or tremor secondary to red nucleus involvement is seen. *Weber syndrome* similarly affects the oculomotor fascicle, but also involves the medial midbrain. Here, penetrating branches of the PCA supplying the cerebral peduncle are affected, leading to defects in the corticospinal and



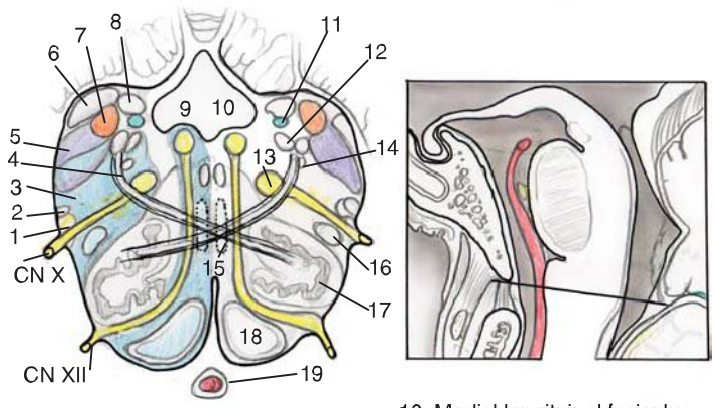


Figure 13.3 The blood vessels supplying the brain. The brainstem is supplied by branches of the vertebral arteries and basilar artery. Note that while this figure shows the internal auditory artery arising directly from the basilar artery, it is commonly a branch off of the anterior inferior cerebellar artery (AICA) instead. corticobulbar tracts, which manifest as contralateral hemiparesis. Dorsal midbrain infarction leads to *Parinaud syndrome* resulting in a tetrad of findings: (a) loss of upward gaze (with loss of smooth pursuit and saccades but with vestibuloocular reflex preservation), (b) large pupils with loss of light reflex, (c) convergence–retraction nystagmus, and (d) lid retraction. Parinaud syndrome is due to lesions affecting the posterior commissure and pretectal region, and can often be identified in an asymptomatic patient on physical examination.

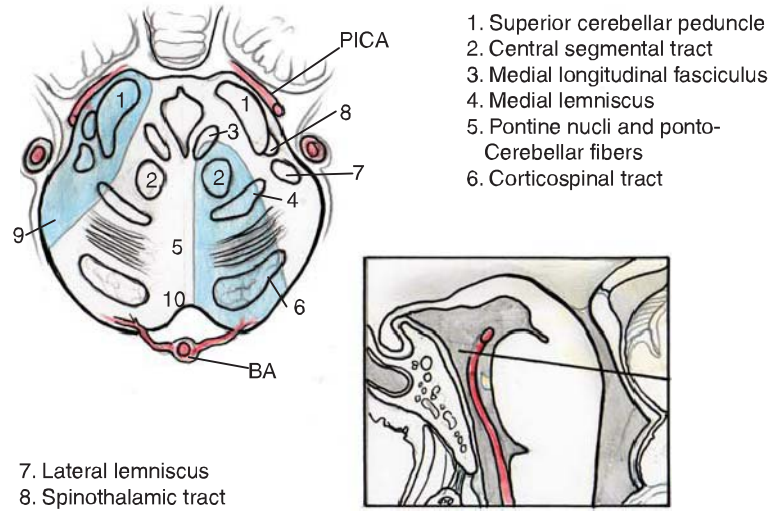
Cerebellar Infarction



Initial symptoms of cerebellar infarction are often nonspecific and many include severe vertigo, vomiting, and ataxia (9). This may be caused by occlusion of the vertebral artery, the posteroinferior cerebellar artery, the anterior inferocerebellar artery, or the SCA. Lack of typical brainstem signs may cause an incorrect diagnosis of an acute peripheral labyrinthine disorder. The key to the diagnosis is the presence of prominent cerebellar signs such as gait ataxia and paretic gaze nystagmus. An early CT scan will often miss posterior fossa ischemia. The diagnostic procedure of choice is magnetic resonance imaging (MRI, Fig. 13.7). After a latent interval of 24 to 96 hours, some patients develop progressive brainstem dysfunction caused by compression by a swelling cerebellum. Progression to quadriplegia, coma, and death may follow, and early surgical decompression should be considered.

Cerebellar Hemorrhage

Hemorrhage into the cerebellum causes neurologic symptoms that often rapidly progress to coma and death (10). The initial symptoms include severe vertigo, vomiting, and ataxia. Similar to cerebellar infarction, brainstem signs may not initially be present, which may cause the condition to be confused with a peripheral vestibular problem. Rapid diagnosis can be made with CT or MRI. Mortality with this condition remains near 25%, with a poor neurologic outcome in many who survive (11). Better initial neurologic status at presentation is highly correlated with a favorable eventual outcome. The value and indications for surgical intervention remain controversial and likely depend on the size and location of the hematoma as well as the patient's symptoms (12).

Figure 13.7 Cerebellar infarction on T2 MRI.

Subarachnoid Hemorrhage

Subarachnoid hemorrhage (SAH) frequently occurs in young and middle-aged adults. Eighty-five percent are caused by aneurysms, most commonly saccular (berry) aneurysm rupture within the Circle of Willis (13,14). Cigarette smoking, age, hypertension, and genetic factors have all been associated with increased risk. Most cases occur before age 55. Presenting symptoms include a sudden explosive headache ("worst headache of one's life"), nuchal rigidity, decreased consciousness, photophobia, meningismus, nausea, and vomiting. The fatality rate is near 50% with many dying prior to arrival at the hospital (14), The seriousness of the condition necessitates a high clinical suspicion to ensure rapid diagnosis and management. Early CT scan is the diagnostic test of choice and may detect subarachnoid blood in 95% of patients if performed within 24 hours from time of rupture (15). If CT is negative and clinical suspicion is high, lumbar puncture should be pursued. Cerebrospinal fluid (CSF) analysis classically shows xanthochromia. If SAH is present, cerebral angiography should be completed with management focused on eliminating the aneurysm from the circulation, which is often addressed using intravascular techniques. Subarachnoid blood is associated with high risk of seizure development, and early seizure prophylaxis should be considered.

Evaluation and Management

Acute spontaneous vertigo is a frequent reason for referral to an otolaryngologist. The possibility of a stroke must be considered, particularly if the patient has vascular

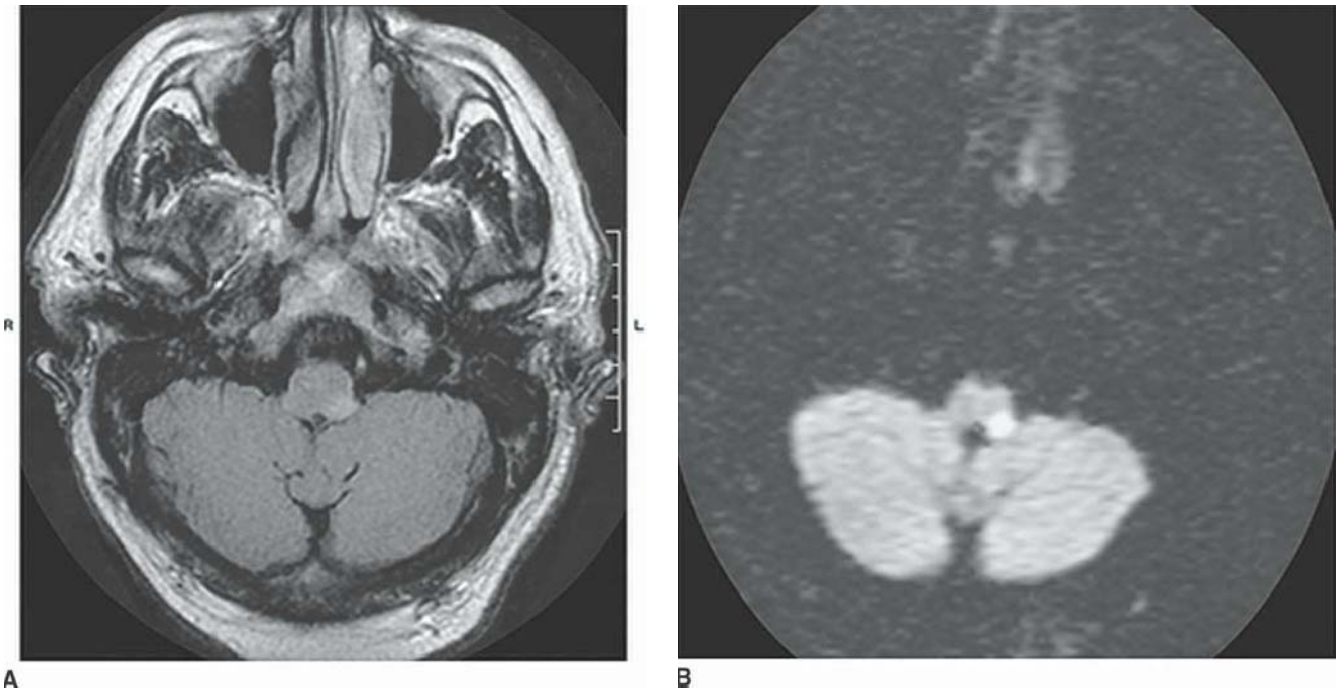

Figure 13.8 MRI of a lateral medullary infarction. **A:** The FLAIR. **B:** Diffusion-weighted images. Both show changes of an acute infarction involving the left dorsolateral medulla. (Courtesy of KD Flemming.)

risk factors or other cranial neuropathies. If the history and examination suggest a vascular disorder, immediate neuroimaging is recommended. CT of the brain without contrast is often the first imaging test because it is widely available and shows intraparenchymal or subarachnoid blood. Hemorrhage can mimic any of the ischemic stroke syndromes and must be excluded with thin-section CT through the cerebellum, brainstem, and fourth ventricle. MRI and MRA are superior to CT for visualizing the vertebrobasilar vessels and their supplied structures since CT is often normal with cerebellar or brainstem infarction. MRI, on the other hand, detects ischemic strokes in the brainstem and cerebellum early on, as well as edema. Diffusion weighted imaging with MRI can now detect infarcts within the first hour of ischemia (Fig. 13.8). MRA has begun to replace conventional angiography in certain circumstances. Vertebral artery dissection and vertebral or basilar stenosis/occlusion can generally be identified with MRA of the cervical vessels (Fig. 13.9).

MIGRAINE

Migraine is understood by the general public to be a headache disorder but the symptoms commonly extend beyond headache. Headaches are usually recurrent and associated with nausea, vomiting, hypersensitivity to light, sound, and smell (16). Neurologic aura is present in a third of migraine patients. Dizziness and pain in the sinus distribution are frequent presentations, making migraine diagnosis important to otolaryngologists. It affects 16% of the population but is much more common in women than men (17). In the prepubertal period, boys with migraine slightly outnumber girls, but at puberty, migraine decreases in boys and increases in girls so that a 2:1 female preponderance is established by adulthood. Migraine typically begins in young adulthood with symptoms developing after age 40 in only 10% of sufferers.

The diagnosis and classification of migraine and other headache disorders has been a controversial issue. The most recent effort of the Headache Classification Committee of the International Headache Society (IHS) (16) sets criteria that allow meaningful comparisons of patients between centers. The IHS classifies the most common type of migraine disorder as migraine with and without aura (Table 13.2). There are also other classified types of migraine, but this is out of the scope of this chapter as they will only rarely be encountered by the otolaryngologist.

Vertigo manifestations are common in migraine patients, and classically are characterized by chronic low-grade dizziness. The definition of migrainous vertigo has also been controversial. Neuhauser et al. (18) proposed criteria for definite migrainous vertigo as (a) episodic vestibular symptoms (rotational vertigo, other illusory self or object motion, positional vertigo, head motion intolerance) of at least moderate severity, (b) migraine according to IHS criteria, (c) at least one of the following migrainous symptoms during at least two vertiginous attacks: migrainous headache, photophobia, phonophobia, visual or other auras, and (d) other causes ruled out by appropriate investigations. Probable migrainous vertigo was chosen for patients

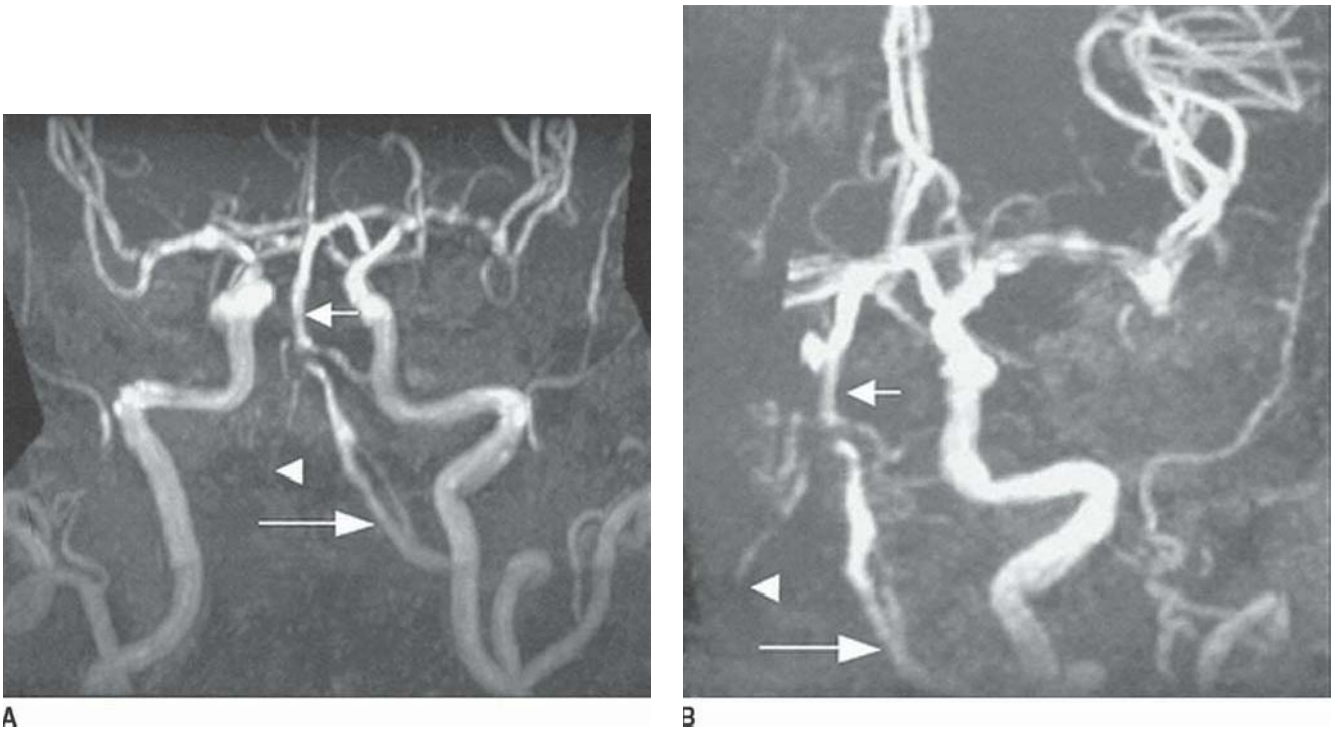

Figure 13.9 **A:** Frontal. **B:** Lateral. Magnetic resonance angiogram showing a severe stenosis at the junction of the left vertebral artery (*long arrow*) and the basilar artery (*short arrow*). The right distal vertebral artery is also occluded (*arrowhead*). (From Lee H. Sudden bilateral simultaneous deafness with vertigo as a sole manifestation of vertebrobasilar insufficiency. *J Neurol Neurosurg Psychiatry* 2003;74:540.)

who did not meet definite criteria but were still believed to have migrainous vertigo as the most likely diagnosis. This requires criteria a and d from the list, plus at least one of the following: migraine according to IHS criteria, migrainous symptoms during vertigo, migraine-specific precipitants of vertigo (e.g., specific foods, sleep irregularities, hormonal changes), or response to antimigraine drugs.

TABLE 13.2 INTERNATIONAL HEADACHE SOCIETY CLASSIFICATION OF MIGRAINE

Migraine without aura

A. At least 5 attacks fulfilling B–D.
B. Headache lasting 4–72 h when untreated.
C. Headache has at least two of the following characteristics: unilateral location, pulsating quality, moderate or severe intensity, aggravation by physical activity.
D. During the headache either nausea and vomiting or photophobia
E. Not attributed to another disorder

Typical aura with migraine headache

A. At least two attacks fulfilling B–D.
B. Fully reversible visual, sensory, or aphasic aura symptoms with no motor weakness
C. At least two of the following: homonymous positive features or unilateral sensory symptoms, at least one symptom develops gradually over more than 5 min, each symptom lasts 5–60 min.
D. Headache follows aura with a free interval of <60 min.
E. Not attributed to another disorder

Vestibular Symptoms

Nonspecific dizziness occurs frequently in patients with either tension or migraine headaches and in itself, does not differentiate between the two groups, although dizziness is more common and severe in migraine sufferers.

Vertigo is extremely common in patients with migraine and occurs in at least a quarter of patients, much higher than the less than 10% prevalence in patients with tension headache. Awareness of the temporal relationship of vertiginous spells to migraine headaches is important. Vertigo does not usually present as an aura immediately preceding the headache. Rather, vertigo is often present without headache symptoms, even though the patients usually have a history of migraine headache.

Motion sickness is common in migraine patients (17,19). Severe motion sickness is approximately five times more common in patients who suffer from migraine. Adult-onset motion sickness should be considered migraine until proven otherwise. A subset of migraine patients experience disabling motion sickness with the need to minimize their head motion, which limits their daily activities. Vestibular stimulation can trigger migraine headaches. Caloric responses in these patients tend to be symmetric and very brisk, often culminating in emesis. If treatment

provides a dramatic response, patients are often surprised at how much they have restricted their lifestyle. Neither the patient nor their physician typically suspects that migraine had any relationship to the other symptoms since patients often only discuss the vestibular symptoms and ignore or discount any symptoms of the underlying problem. Prophylactic migraine therapy often yields dramatic improvement.

Auditory Symptoms

Migraine patients are frequently sensitive to loud sounds, which may trigger or exacerbate headache or vertigo symptoms. Auditory symptoms such as hearing loss and tinnitus are occasionally present and are more prominent in patients with basilar migraine.

Migraine Associated with Neurologic Symptoms

The coexistence of migraine with neurologic symptoms suggestive of brainstem pathology defines basilar migraine (20), which is due to presumed ischemia in the distribution of the basilar artery (21). This subtype of migraine is similar to classic migraine in that it consists of an aura followed by a severe headache; however, vertigo symptoms are usually present.

Migraine can be diagnosed in the absence of headaches. Patients sometimes develop typical headaches later in life, or have auras that are only intermittently related to headaches. A history of motion sickness, premenstrual clustering of attacks, or headaches associated with some attacks is frequently present. Personal or family history of migraine is also helpful in diagnosing these patients.

Etiology

Current theory of the genesis of migraine implicates a neural origin with spreading of depression activity (22), although the neurophysiology is far from completely understood.

Family history of migraine is present in approximately 40% to 90% of affected individuals. When migraine patients with and without aura are examined separately, patients who have migraine with aura are more likely to have affected family members. In twin studies, the concordance of migraine is only 10% to 34% depending on the country, suggesting that both genetic and environmental factors play a role (23).

Familial hemiplegic migraine (FHM) is a rare type of migraine affecting only 0.01% of the general population (24). However, the underlying cellular cause is relatively well understood. Unlike most migraine, FHM has a clear autosomal dominant pattern of inheritance. So far, mutations have been found in three different genes that determine neuronal excitability.

Management

Migraine treatment has traditionally been dominated by management of headache symptoms and can be divided into symptomatic and prophylactic management strategies. Symptomatic interventions are useful in ameliorating the acute attack, while prophylactic interventions are designed to reduce the frequency or severity of attacks. Symptomatic management includes analgesics, antiemetics, antivertiginous drugs, sedatives, and vasoconstrictors. In many patients, over-the-counter analgesics (such as ibuprofen, aspirin, or acetaminophen) and rest are sufficient to relieve headache symptoms.

Nutrition may play a significant role in the frequency and severity of migraine headaches and migraine-associated dizziness. Riboflavin (vitamin B_2) and high-dose magnesium have been shown to have a therapeutic effect on migraine. Suggested mechanisms include inhibiting platelet aggregation, counteracting vasospasm, stabilizing cell membranes, and anti-inflammatory effects.

Food sensitivity may be a migraine trigger in a significant number of patients with migraine symptoms (25). Although some patients have observed that consuming a certain food will reliably provoke a headache, the effect of diet is often more subtle. Foods, which should be avoided include red wine, aged cheeses, beer, chocolate, caffeine, and yogurt (26). Dietary modification may be considered as first-line therapy for migraine prophylaxis (Fig. 13.10.)

Vestibular migraine symptoms are often continuous and not directly related to the headache symptoms; however, treatment of vestibular migraine mirrors that of traditional migraine prophylaxis. Because migraine-associated dizziness is often much more frequent than the headaches, symptomatic treatment effective for headaches is usually not effective for dizziness.

Sumatriptan (Imitrex), a 5HT1D receptor-agonist, has become the principal drug to abort severe migraine headache. Initial trials indicate that in 90% of cases the drug effectively aborts migraine headache symptoms within an hour of onset when used subcutaneously and 70% to 85% may be aborted if used within 2 hours. Despite efficacy in relief of early migraine headaches, breakthrough is common and the drug has limited efficacy for concurrent vestibular symptoms.

Propranolol (Inderal) is the most common drug for preventing migraine episodes. The medication is contraindicated in patients with asthma, congestive heart failure, peripheral vascular disease, diabetes, and hypothyroidism. Principal side effects include fatigue, lethargy, and orthostasis. Side effects are minimized by slowly increasing the dose from a low starting level. Because of these side effects, the medication is poorly tolerated in patients who do not have preexisting hypertension.

Tricyclic antidepressants are currently the mainstay of migraine prophylaxis. Amitriptyline is perhaps the most studied drug in this category with several studies showing

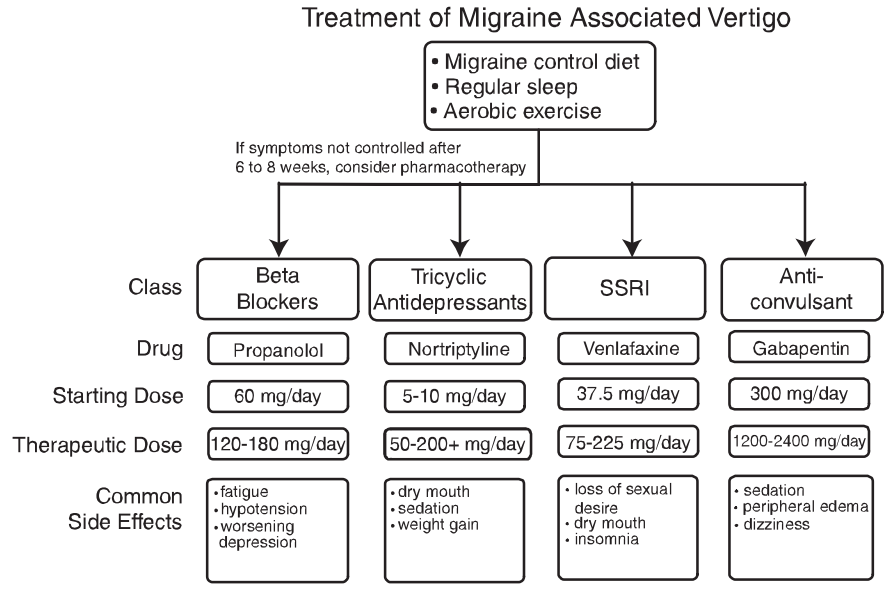

Figure 13.10 Flowchart of suggested migraine treatment. Lifestyle modification is usually a good first option since it is not associated with side effects and will provide symptomatic improvement in most patients. Pharmacotherapy should be considered if more conservative measures fail.

its efficacy (27). However, the newer drug nortriptyline is usually better tolerated due to the milder side effect profile. Starting doses are usually 10 to 25 mg, which is usually given at bedtime to minimize sedation and anticholinergic activity. Weight gain is a side effect that limits compliance with therapy in some patients. Therapeutic doses are usually 50 to 100 mg, with some patients who also suffer from depressive symptoms requiring doses of up to 200 mg.

Use of selective serotonin reuptake inhibitors (SSRIs) for treatment of migraine remains controversial. However, in patients with chronic subjective dizziness as their primary symptom, SSRIs have some efficacy (28).

Gabapentin (Neurontin) has been effective at dosages of 1,200 to 2,400 mg/d (29), which is usually divided into three daily doses. Dizziness, peripheral edema, and somnolence are common side effects, which limit their use.

NEUROMUSCULAR DISORDERS

Amyotrophic Lateral Sclerosis

Amyotrophic lateral sclerosis (ALS) is a progressive neurodegenerative disease of undetermined etiology. In the United States, ALS is often referred to as Lou Gehrig disease after the well-known baseball player who was diagnosed with the disease in 1939. Gehrig had been known as the "The Iron Horse" for his well-rounded play and durability. However, with decreased strength and difficulties with coordination and stamina, the world watched as this illness affected the strongest of men.

Disease incidence in the United States is approximately 2 per 100,000 with a prevalence rate of 6 per 100,000. Men are more often affected than women. While the sporadic form is most common, an autosomal dominant inheritance pattern is identified in 5% to 10% of patients with ALS, and this form of the disease is referred to as familial ALS. In this disease subtype, mutations in an enzyme called copper/zinc superoxide dismutase (SOD1) have been identified in up to 20% of patients and have been the focus of many research efforts. In the sporadic form, many neurologists and researchers have identified a link between disease and glutamate toxicity due to decreased glutamate transport, leaving the neurons at risk for increased calcium influx and subsequent cell toxicity and apoptosis.

ALS affects both the upper and lower motor neurons of the CNS. It leads to progressive muscle atrophy as well as spasticity. Though the illness typically begins in an area of contiguous peripheral muscles (upper extremity > lower extremity), manifestations in the head and neck can be the first signs of illness in up to 28% of patients (30). This, bulbar-onset form of the disease may present with slurred speech, inability to project the voice, hoarseness, or dysphagia, and is associated with a more rapid progression (31). Tongue atrophy and fasciculations are commonly seen and may be first noticed by the otolaryngologist who can assist in diagnosis. Extraocular muscles are usually spared, and if weakness is noted, other diagnoses should be pursued. Unlike the classic form of ALS, bulbar-onset ALS has a slight female predominance.

Aspiration is a common and significant symptom of ALS that can lead to infection and further respiratory compromise. Thus, prevention of aspiration is one of the mainstays of therapy. Weakness of the cervical muscles is also a common manifestation that can result in worsening dysphagia, sialorrhea, and more-pronounced head-droop. Dysphagia and reduced caloric intake hastens general muscle atrophy, and, a focus on maintenance of nutritional status is quite important with consideration of gastric feeding if necessary. Diaphragmatic and respiratory muscle weakness often results in the need for ventilator support, and respiratory failure is the most common cause of death.

TABLE 13.3 SYMPTOMATIC TREATMENT OF HEAD AND NECK MANIFESTATIONS OF ALS

Symptom	Pharmacotherapy	Other Therapy
Jaw cramps	Benzodiazepines	Botox injection of masseters
	Quinine sulfate	PT
	Baclofen	Massage
	Vitamin E	
Pseudobulbar affect	Tricyclic antidepressants	
	SSRIs	
	Carbidopa/levodopa	
	Lithium	
	Venlafaxine	
	Quinidine/dextromethorphan	
Sialorrhea	Glycopyrrolate	Botox injections of salivary glands
	Carbamazepine	Parotid radiation
	Diphenhydramine	Reassurance
	Scopolamine patch	Suction machine
	Hyoscyamine sulfate	
	Tricyclic antidepressants	
	Atropine	
Thick secretions	Guaifenesin	Cool mist humidifier
	Nebulized *N*-acetylcysteine	Oscillation therapy
	Nebulized saline

Aspiration	Motility agents	Tracheostomy
		Modification of diet
		Swallow therapy
		Tracheal diversion
Voice disturbance	Antireflux medications	Tracheostomy if obstruction
	Sublingual lorazepam	Communication boards
		Morse code
		Use of computer systems
		Use of infrared eye movement
		Voice therapy
Respiratory failure	Morphine sulfate	Noninvasive positive-pressure ventilation
	Bronchodilators	Tracheostomy w/ventilation

Prognosis of ALS is dismal with an average 5-year survival rate of 22% and 10-year survival of 9.4%. Median survival is 2 to 3 years (32). Treatment is focused primarily on supportive care and symptom management (Table 13.3). Riluzole (Rilutek) and other antiglutamatergic agents are pharmacologic therapies that are often used as they have been the only agents shown to impact survival. Studies have shown increased survival in patients taking Riluzole compared to placebo, but the survival benefit is small and is more often seen in patients with bulbar-onset disease. A recent Cochrane meta-analysis showed that 100 mg of Riluzole daily was associated with a 9% increase in probability of surviving 1 year (33). Because of the complexity of care and the many systems involved, treatment by a multidisciplinary team has been highly regarded. This includes physicians, nutritionists, speech pathologists, dietitians, and occupational therapists to name a few of the participants. Treatment in multidisciplinary ALS clinics has been associated with decreased hospital admissions and longer survival (1,080 vs. 775 days, $P = 0.008$) (34), and therefore should be strongly considered in management of patients with ALS.

Pseudobulbar Palsy

Pseudobulbar palsy, also called spastic bulbar palsy, is a disease affecting the corticobulbar tracts bilaterally. The corticobulbar tracts help control the motor nuclei of CN V, VII, IX, and XII, which play a role in deglutition, mastication, and speech. Thus, patients may experience hyperreflexia and spasticity of the pharynx, larynx, lips, tongue, and palate. The voice may sound spastic or strained (not unlike spasmodic dysphonia) and speech may be slow and effortful. Emotional lability is also a feature of this illness that can be embarrassing for many patients as they may demonstrate pathologic laughter, grimaces, or crying. Treatment is typically supportive. Baclofen has been used for spasticity, and SSRIs as well as tricyclic antidepressants

have had some effect on decreasing emotional outbursts. A combination of dextromethorphan and quinidine agent is under investigation as it did decrease emotional outbursts in patients with ALS, and was therefore thought to be helpful in pseudobulbar palsy (35). Pseudobulbar palsy must be differentiated from bulbar palsy, which affects the lower motor neurons of these motor nuclei directly.

Guillain-Barré Syndrome

Guillain-Barré syndrome (GBS) is an acute inflammatory demyelinating polyradiculoneuropathy (AIDP) that, in its most common form, has been linked to upper respiratory or gastrointestinal infection. *Campylobacter jejuni* is the bacteria most often identified in relation to GBS; however, several viral agents have also been implicated. GBS is characterized by symmetrical motor weakness, paresthesias, and areflexia that begin in the lower extremities and ascend to affect the upper extremities, oropharyngeal structures, and respiratory muscles. This progression can occur within hours to days, and if it continues for over 4 weeks is considered subacute (4 to 10 weeks) or chronic (greater than 10 weeks) AIDP (subacute IDP, chronic IDP). Sensory impairment is minimal and is usually limited to distal loss of vibratory sense. Cranial nerves are commonly affected with up to 50% of patients experiencing bilateral facial paresis. Areas of demyelination have been found on the peripheral nerves leading to slowed conduction time on electromyography. This conduction deficit, in addition to the CSF findings on lumbar puncture (high protein with otherwise decreased cellularity of the fluid), aids in diagnosis. The proportion of patients with severe respiratory failure requiring ventilation ranges from 12% to 30% (32) and seems to increase in age. Plasma exchange and high-dose IVIG therapy have been shown to be equally effective in reducing the harmful effects of autoantibodies and shortening recovery time (36). Corticosteroids have not shown a significant benefit and are not recommended. Treatment is most effective when started within 2 weeks of disease onset. Most patients do recover from the illness with 70% showing full recovery in 1 year and 82% at 2 years; however, some patients do have residual sequelae and others may recur (recurrence rate = 5%) Improvements in critical care and ventilator use have decreased the mortality rate of this disease from 33% to 5% to 10% (32).

Multiple Sclerosis

Multiple sclerosis (MS) is an inflammatory demyelinating disease of the CNS that affects younger patients, especially women in their 20s to 40s. The female to male ratio of those affected is approximately 1.7:1. The etiology of MS is still unclear, though the current theory is that the etiology is multifactorial with a genetic predisposition needing an environmental trigger to activate the disease process leading to a continued autoimmune process. Several HLA types have been correlated with MS, with some related to increased risk of disease (DRB1*15 and DRB1*03) and others offering a potential protective role (DRB1*14 and DRB1*07) (37). That viral infection plays a role in development of MS has been speculated; however, studies looking to identify a viral genome have not been successful and therefore much controversy surrounds this topic. Other environmental triggers have been evaluated, and geographic studies have provided some interesting findings, namely that disease prevalence seems to increase with distance from the equator. Migration studies demonstrate that when moving from a high-risk to low-risk area during adulthood, the original risk is maintained. However, when immigrating in childhood, the risk profile takes on that of the newly inhabited area. These studies offer evidence that environmental factors are certainly involved in MS development.

MS is characterized by demyelination of white matter areas within the CNS with relative axonal sparing, leading to slower conduction times of action potentials. Myelin basic protein (MBP) is a candidate for the target of T cells attack; however, other protein components of myelin may also be involved. As demyelination occurs in a particular area, the threshold for conduction is altered, leading to transient symptoms (i.e., Uhthoff phenomenon—blurring of vision during times of strenuous activity or increase in temperature). Similarly, de novo action potentials from mechanical activation of demyelinated areas can lead to electric shock-like sensations with muscle flexion (Lhermitte phenomenon). Completely spontaneous action potentials in these areas may contribute to trigeminal neuralgia, which is commonly seen in MS patients.

Symptom development and the clinical course of MS are quite variable, and several forms of the disease exist; however, the relapsing–remitting form is the most common. This pattern demonstrates acute exacerbations with periods of remission where the symptoms resolve either partially or completely. A hallmark of MS is that symptoms are "disseminated in both time and space" (i.e., more than one area of the CNS is involved and at more than one time point). Both motor and sensory systems are involved, and head and neck manifestations are plentiful, with cranial neuropathies often representing brainstem lesions. Optic neuritis (an episode of decreased visual acuity with associated pain [especially with eye movement], alterations in color perception, and afferent pupillary defect [Marcus-Gunn pupil]) is a common initial presentation of MS in approximately 17% to 19% of patients (38). Nystagmus, saccadic eye movements, loss of smooth pursuit, oscillopsia, and internuclear ophthalmoplegia (loss of ability to link the nuclei of CN III and CN VI together during lateral gaze due to lesions in the medial longitudinal fasciculus) are other common ocular manifestations of MS. The nystagmus seen in MS patients is called acquired pendular nystagmus and is characterized by small-amplitude oscillations. Impairment of facial sensation including trigeminal neuralgia, facial myokymia (wave-like twitching of facial

muscles), hemifacial spasm, and facial paresis may also be seen. Vertigo affects 30% to 50% of patients and hearing loss is usually unilateral, but is an uncommon finding (32). Lower cranial nerve involvement typically presents only in late-stage disease and displays an upper motor neuron–type defect leading to dysarthria and dysphagia.

MS affects many areas outside of the head and neck. Cerebellar dysfunction presents with dysmetria, ataxic gait, intention tremor, lack of upper extremity coordination, and slurred speech. Charcot triad represents the combination of nystagmus, scanning speech, and intention tremor seen in many MS patients. Motor involvement with paraparesis, spasticity, and exaggerated deep tendon reflexes is often seen. Various other systems are also affected throughout the body including bowel/bladder control, heat intolerance, fatigue, cognitive impairment, affective disorders, pain, and difficulties with memory and coordination.

Because of the variable range in presentation of MS, diagnosis is often delayed and can be quite difficult. The diagnosis of MS is made clinically with assistance from laboratory studies and neuroimaging. The McDonald criteria, which were recently revised in 2010, help clarify diagnosis by combining clinical, laboratory and imaging parameters (39). MRI of the brain and spinal cord depicts areas of demyelination and edema as seen on T2 imaging and "black holes" representing axonal loss on T1 imaging. MS plaques are seen in characteristic areas within the periventricular white matter and corpus callosum (Dawson fingers). Gadolinium enhancement can be used to demonstrate more acute lesions. Aside from neuroimaging, CSF analysis, as well as evoked potential testing, can assist in diagnosis of MS. CSF is often normal in patients with MS, but the presence of a lymphocytic predominance, elevated immunoglobulin, or oligoclonal bands is a helpful adjunct to MS diagnosis. Electrical conduction studies such as evoked potential testing (brainstem auditory, visual, or somatosensory) are not specific for MS but can show increased latencies consistent with demyelination. They are particularly helpful for detection of subclinical disease.

Management of MS focuses on treatment of acute exacerbations, reduction in lasting sequelae, decreasing the number of relapses, and supportive care. In the acute setting, corticosteroids are the mainstay of therapy. For overall disease management, the "ABCs" of immunomodulating therapy are often used, which include Avonex (interferon beta-1a), Betaseron, and Copaxone (glatiramer acetate). The first interferon approved by the FDA for treatment of MS in 1993 was Betaseron (interferon beta-1b), which decreased the rate of relapses by 34% after 2 years (32). Copaxone differs from the interferons, but is another first-line therapy shown to decrease relapse rate by simulating MBP and acting as a decoy for the body's immune system. Novantrone (Mitoxantrone) is a chemotherapeutic agent used in the progressive form of the disease. The newest agent, now approved as single-agent therapy for relapsing-remitting MS, is Tysabri (Natalizumab), a monoclonal antibody directed against a4 integrin adhesion molecules. This inhibits trafficking of lymphocytes from the blood into the CNS, and has been shown to decrease the relapse rate as well as to slow disease progression. A few cases of progressive multifocal leukoencephalopathy were associated with Tysabri treatment (concurrent with interferon therapy) leading to the product being pulled from shelves. It is been reapproved as monotherapy for patients who have failed or not tolerated ABC therapy. Other agents can be used to target symptoms directly and the use of a multidisciplinary team including occupational therapists, psychiatrists, physical therapists, and speech pathologists among others has also been recommended.

Autoimmune Neurologic Diseases

Many autoimmune diseases may manifest as head and neck pathology. A comprehensive description of these illnesses is beyond the realm of this chapter; however, we will touch on several of the most common pathologies to introduce the reader to this interesting discussion.

Myasthenia Gravis

Myasthenia gravis (MG) is a progressive autoimmune disorder and is the most common primary disorder of neuromuscular transmission. The highest incidence is seen in women in their 20s and 30s and men in their 60s. The pathogenesis of this disease relates to the development of autoantibodies to nicotinic acetylcholine (Ach) receptors affecting the neuromuscular junction of striated muscles. Detection of these autoantibodies in the serum of patients is 80% to 90% sensitive for diagnosis of MG. Sensation and reflex movements are not impaired.

Symptoms of MG usually begin with small muscle groups, especially the ocular muscles. In fact, 90% of patients have some ocular involvement, and the medial rectus muscle is most affected. Approximately, 20% of patients demonstrate ocular myasthenia that never progresses to limb muscles and affects ocular muscles alone (40). With either form of disease, patients usually report diplopia, eye fatigue, ptosis, and blurred vision that worsen as the day progresses. Symptoms are further worsened during times of eye strain (i.e., watching television, bright sunlight, driving). Other head and neck muscles are also affected, including the pharyngeal muscles among others. For example, jaw muscle weakness and a sad facial appearance due to facial muscle weakness may also be noted. Cricopharyngeal involvement resulting in dysphagia and velopharyngeal insufficiency has also frequently been described. Symptoms are more pronounced after repetitive use of the particular muscle group. Respiratory dysfunction is atypical, except in the context of anti-MuSK antibody–positive myasthenia, which mimics motor neuron diseases (41).

Diagnosis of MG can be made by a combination of methods including antibody detection, edrophonium challenge, and electrodiagnostic studies. Even so, diagnosis is often delayed due to the fluctuation of symptoms. An Edrophonium challenge test acts to increase Ach in the neuromuscular junction by inhibiting acetylcholinesterase, thus allowing prolonged interaction with the Ach receptor. Weakness that improves after acetylcholinesterase inhibitors can be seen in patients with MG, but can also be present in other disease entities such as Lambert-Eaton syndrome. Patients with ocular myasthenia show decreased rates of response to edrophonium challenge compared to patients with generalized myasthenia; therefore. Other methods of detection are important to address. As discussed above, serum assay for autoantibodies to the acetylcholine receptor along with clinical symptoms can confirm the diagnosis. However, the lack of these antibodies can be seen early in the disease, and thus, should be retested 6 to 12 months after symptom onset if the initial testing is negative. Ocular cooling, or the "ice pack test" has been shown to improve lid ptosis after application for 2 minutes. This test shows 89% sensitivity and is helpful for detection of ocular myasthenia, particularly in the context of a normal edrophonium challenge (42). Finally, electrodiagnostic testing includes repetitive nerve stimulation (RNS) with comparison of the amplitude of the compound action potential from the first stimulus to the fourth or fifth stimulus. A 10% decrease in amplitude over this period is reliable in diagnosis. Single-fiber electromyography can be performed when RNS is negative but a high clinical suspicion for a neuromuscular junction disorder is present. This more sensitive test shows increased jitter in at least one muscle in almost all patients with MG. Sensitivity is higher with generalized myasthenia compared to ocular myasthenia alone, but specificity remains high (40).

Thymic hyperplasia (affecting 70% of patients) and thymoma (affecting 10% of patients) have been associated with MG and play a role in disease management. Increased activity suggests an ongoing immune response. Most thymomas are benign, though malignancy has been described. Thymectomy improves the clinical course of MG, though this has not been clearly shown in prospective controlled trials. Despite this, current recommendations include thymectomy for patients with MG whose symptoms began before the age of 60, except in the case of purely ocular myasthenia. Younger women show the best response after thymectomy; however, overall response is variable especially in those with ocular myasthenia or thymoma.

Other therapeutic measures to control MG include cholinesterase inhibitors (including pyridostigmine and neostigmine), corticosteroids, immunosuppressants (e.g. azathioprine), plasma exchange, and IVIG. With the current treatment recommendations, mortality rate of myasthenia approaches zero, and patients lead near-normal lives with adequate treatment.

Susac Syndrome

Susac syndrome was first described in 1979 by John Susac and consists of a triad of branch retinal artery occlusion (BRAO), encephalopathy, and hearing loss. Young women (age 20 to 40) are most commonly affected, but this entity has been described throughout a wide age range (age 7 to 72). Susac syndrome has been characterized as a small-vessel autoimmune endotheliopathy. The precapillary arterioles of the brain, cochlea, semicircular canals, and retina are affected leading to arteriolar occlusion with subsequent microinfarction of the involved end organs.

Symptoms of this disorder include headache (often with migrainous characteristics), bizarre behavior changes, cognitive changes, memory loss, confusion, tinnitus, vertigo, sensorineural hearing loss, and visual defects. Two subsets of the disease have been described: (a) the encephalopathic form and (b) the recurrent BRAO form. The encephalopathic form is the most common and more easily recognized subtype in which encephalopathic symptoms are the dominating clinical features. These patients often develop BRAO and/or hearing loss as well; however, these need not be present at the initial time of diagnosis. This form is often self-limited, but active disease duration ranges from 2 months to almost 20 years. However, several studies have described late manifestations and residual deficits. Thus, this disorder cannot be taken lightly, and early treatment is recommended to prevent sequelae. The recurrent BRAO subtype is less severe, though more often a chronic disorder with a fluctuating clinical course. It is characterized by repeated episodes of retinal vasculopathy that can range from symptomatic occlusive disease to asymptomatic arteriolar wall hyperfluorescence. Symptoms of ocular symptomatology include black spots within the visual field and scintillating scotoma. Hearing loss is typically sensorineural in nature. The onset of hearing loss is quite variable and can manifest acutely or follow an insidious or even fluctuating course. A loss of wave I on brainstem auditory-evoked response testing may be seen indicating cochlear infarction. Low tones are affected first and the resulting hearing loss can be severe or even profound.

Diagnosis of Susac syndrome is often difficult, especially when the full triad of symptoms is not present. Both MRI and retinal fluorescein angiography are helpful in diagnosis. Due to the predominance of white matter changes and similarities of MRI findings, it is often misdiagnosed as MS or acute disseminated encephalomyelitis. The corpus callosum is always involved in Susac syndrome. Sagittal T1 and T2 FLAIR images depict microinfarctions of this area that are described as "snowballs" or "holes" by some (43) (Fig. 13.11) There is a predilection for the central areas and the roof of the corpus callosum to be involved in this syndrome. This helps differentiate Susac syndrome from MS, which tends to involve the periventricular areas. A new MRI finding described in 2010 by Rennebohm et al. is a "string of pearls" seen best on diffusion weighted

Figure 13.11 Sagittal T1 MRI image demonstrating microinfarction in the corpus callosum.

axial MRI, representing microinfarctions along the internal capsule. Unlike patients with MS, grey matter or cortical changes can be seen in as many as 70% of patients with Susac syndrome (44). Fluorescein angiography (FA) is helpful to evaluate for retinal vasculopathy and can help identify even subtle changes that affect only the periphery or asymptomatic lesions. Further, serial FA has been used to help determine treatment response and clinical course.

Treatment of Susac syndrome should be initiated early to help prevent development of residual sequelae. Immunosuppression is the key to disease management with corticosteroids being the first-line therapy. IVIG and cyclophosphamide have also been utilized with a clear clinical response in severe cases. Recent descriptions of monoclonal antibody therapy, specifically anti-TNF-alpha therapy (infliximab), have shown dramatic effects; however, no adequate clinical trials have yet been conducted. Other therapies targeting the vasculature have been described including aspirin, calcium-channel blockers, and anticoagulants. Given the rarity of this disease entity, few trials have been conducted to compare various therapeutic regimens with sound evidence-based methodology. Symptoms-specific management targeting visual changes or hearing loss have been attempted. Hyperbaric oxygen therapy was shown by Li et al. (45) to reverse visual loss in a patient. Cochlear implantation may be a treatment option for patients who have significant bilateral hearing loss.

NEOPLASMS

Space-occupying lesions can induce otolaryngologic symptoms by compressing or by destroying neural tissue within the temporal bone, in the cerebellopontine angle, or intra-axially within the brainstem and cerebellum. Symptoms can also be produced or increased by vascular compression.

Vestibular Schwannomas (Acoustic Neuromas)

Vestibular schwannomas are slow-growing benign neoplasms most often seen at the cerebellopontine angle (Fig. 13.12). They can present asymmetric hearing loss, tinnitus, and with vertigo. Although, vertigo is present in less than 20% of patients with vestibular schwannomas (46). It can be disabling (47). These tumors can also present with hyperventilation-induced vertigo in the absence of hearing loss (48). Discussion of the diagnosis and treatment of vestibular neuromas is covered in depth elsewhere in this text.

Brainstem Neoplasms

Gliomas of the brainstem usually grow slowly and infiltrate the brainstem nuclei and fiber tracts, producing progressive symptoms and signs. Astrocytoma is the most common form of glioma. The typical history is relentlessly progressive involvement of one brainstem center after another, often causing death with the destruction of the vital cardiorespiratory centers of the medulla. These tumors are 5 to 10 times more common in children than adults. Vestibular and cochlear signs and symptoms occur in about half of patients but the spectrum of findings makes a brainstem origin clear. In the modern era, imaging studies such as

Figure 13.12 A T1 MRI with gadolinium contrast demonstrating a 2.2 cm vestibular schwannoma in the left internal auditory canal and cerebropontine angle.

CT or MRI are usually obtained when the first symptoms present, making the diagnosis obvious.

Tumors originating in the fourth ventricle can compress the vestibular nuclei producing vestibular symptoms. An attack of headache, vertigo, vomiting, and visual loss may result from a change in head position, producing transient CSF obstruction (Bruns syndrome). Positional vertigo and nystagmus may be the presenting symptom and sign. Other fourth ventricular tumors that produce similar clinical pictures include ependymomas, medulloblastomas, papillomas, teratomas, epidermoid cysts, and cysticercosis. The diagnosis of a fourth ventricular mass is made readily with MRI and CT scanning, but frequently the exact nature of the tumor cannot be determined prior to surgical exploration and biopsy. Complete removal of tumor should be achieved when possible. Medulloblastomas are particularly sensitive to radiotherapy (49).

Cerebellar Neoplasm

Dizziness is a common clinical manifestation of a posterior fossa tumor occurring in 81% of patients (50). Half of patients with posterior fossa tumors have spontaneous nystagmus, and a third lack caloric responses. Other common symptoms of cerebellar tumors include tinnitus, hearing loss, headache, nausea/vomiting, and ataxia. Gliomas of the cerebellum may be relatively silent until they become large enough to obstruct CSF circulation or compress the brainstem. Positional vertigo is occasionally the initial symptom of a cerebellar tumor (51). Paroxysmal positional nystagmus, when present, is atypical because it can be induced in several different positions and is nonfatigable. Tumors that can produce these signs and symptoms include gliomas, teratomas, hemangiomas, and hemangioblastomas. Each of these tumors has a characteristic appearance on MRI and CT scanning, although occasionally, the exact tumor type cannot be determined before surgical biopsy.

CHIARI MALFORMATION

Chiari malformations are characterized by herniation of the contents of the posterior cranial fossa through the foramen magnum. They can be divided into two forms: Chiari types I and II.

Chiari type I is more mild and common. Symptoms are usually delayed until age 25 to 35 years. Affected individuals often have subtle neurologic symptoms that are not associated with other developmental defects. Diagnosis is made through CT scan or MRI reconstructed in the sagittal plane, which may demonstrate deformation of the cerebellar tonsils more than 5 mm caudally through the foramen magnum (Fig. 13.13). Symptoms often include upper extremity weakness, sensory loss, and pain. Occipital headaches, which are exacerbated by coughing, sneezing, bending over, or lifting, are also common. Dizziness is also frequently described and nystagmus may be present.

Figure 13.13 Magnetic resonance image of a patient with Chiari type I malformation, with cerebellar tonsils (*arrow*) below foramen magnum.

Patients can also present to an otolaryngologist with dysphagia, aspiration, or hoarseness due to involvement of the lower cranial nerves (CN IX, X, and XII).

Chiari type II manifests in the first few months due to associated hydrocephalus and other CNS malformations such as meningomyelocele.

NORMAL-PRESSURE HYDROCEPHALUS

Idiopathic normal-pressure hydrocephalus classically presents with the triad of dementia, urinary incontinence, and gait or balance disturbance. However, these symptoms represent the more severe end of the clinical spectrum, and more subtle cases can present with only mild gait or balance symptoms (52); thus an otolaryngology consultation may be requested. Cognitive symptoms are also common, but may be mild. Patients usually become symptomatic after age 60. Diagnosis requires an imaging study demonstrating nonobstructive ventricular enlargement disproportionate to cerebral atrophy.

HIGHLIGHTS

- Many neurologic disorders present with symptoms in the head and neck region, and a screening neurologic exam can help to identify some of these disorders.
- The cranial nerves contain fibers involved in sensation, motor function, and the special senses and are an integral part of the head and neck examination.

- Neurologic conditions can have a wide variety of manifestations in the head and neck leading to symptoms of dysphagia, vertigo, dysphonia, hearing loss, and other cranial neuropathies.
- Cranial neuropathies can be a sign of cerebrovascular disease. The deficits reflect the territory of blood supply to the affected area, which aids in diagnosis.
- Migraine is more than just a headache and can present to the otolaryngologist with various symptoms including vertigo.
- Management of migraine is complex and includes dietary and lifestyle modifications as well as a variety of pharmacotherapeutic agents including beta-blockers, tricyclic antidepressants, SSRIs, and other drugs.
- ALS is a progressive neuromuscular disorder that involves both upper and lower motor neurons and may present with bulbar symptoms including dysphagia and tongue atrophy and fasciculations.
- The otolaryngologist should be aware that MS, GBS, MG, and Pseudobulbar Palsy commonly have symptoms that involve the head and neck. The otolaryngologist may play a role in symptom management in patients with these disorders as part of a multidisciplinary medical team.
- Susac syndrome is rare and symptoms include the triad of retinal artery occlusion, hearing loss, and encephalopathy.
- Neoplasms of the CNS may induce otolaryngologic symptoms by compressing or destroying neural tissue within the temporal bone, in the cerebellopontine angle, or intra-axially within the brainstem and cerebellum or by vascular compression.
- Disorders of the craniovertebral junction may present as vertigo with patient's seeking initial consultation by an otolaryngologist.
- It is important for the general otolaryngologist to recognize key features of common neurologic disorders in order to initiate management or arrange for proper and prompt referral to the appropriate physician.

Ophthalmology

14

Jean Edwards Holt *G. Richard Holt*

Abnormalities of the ocular structures produce visual dysfunction, altered appearance, pain, or systemic symptoms. Many persons believe vision to be the most important and comprehensive of the senses. Decreased visual acuity can indicate a blinding eye disease that can be controlled with restoration of vision, a systemic disease that can endanger life if not detected and managed, a tumor or other disorder of the central nervous system that can threaten vision and life, or a simple refractive error, correction of which simplifies the patient's life. Ocular symptoms bring the patient rapidly to the physician because the eyes are the focus of a patient's perception, and alterations in these structures usually are not ignored.

The otolaryngologist–head and neck surgeon often joins the ophthalmologist in a team approach to care for a patient with congenital or acquired abnormalities of the orbit, adnexa, and periorbital structures. Appreciation of the fundamental concepts of vision, ocular anatomy and physiology, and local and systemic disorders is essential to direct care or assist in caring for a patient with ophthalmic problems (Fig. 14.1). Consultation with an ophthalmologist is mandatory for many disorders and such a joint approach is beneficial to patient care. This chapter highlights the most common disorders seen by otolaryngologist–head and neck surgeons, which have orbital, adnexal, and ocular implications. Also discussed are the best diagnostic studies for the identification of ophthalmologic and orbital disorders, trauma, and tumors.

THE EYE EXAMINATION

The three indications for performing an ocular examination include:

1. Presenting symptoms clearly related to ocular structures, such as pain in the eye and decreased vision
2. Presymptomatic screening to detect controllable eye disease, such as amblyopia and glaucoma
3. Evaluation or diagnosis of systemic disease mirrored in the eye, such as retinopathy and neuropathy in diabetes

With these goals in mind, it is obvious that testing the function of the visual system and examining the eyes should be part of any complete head and neck examination (1).

An eye examination begins with obtaining a history related to the symptoms. Relevant areas are chronology, eye history, family history, concurrent systemic diseases, present use of medications, and existence of allergies. Ocular symptoms usually can be classified into three groups—altered visual function, abnormal sensation, or altered appearance. Abnormalities in visual functioning generally reduce vision, cause superimposed visual phenomena, or produce diplopia. Abnormal sensation in or around the eye can take many forms—deep pain, which signifies intraocular or orbital inflammation; foreign-body pain related to trauma; superficial pain of mild conjunctivitis; vague discomfort known as *asthenopia*, or eyestrain, with prolonged, intensive use of the eyes; headache related to neurologic disease or tension; or photophobia or ocular pain with exposure to light, most commonly related to corneal abnormalities. *Altered appearance* usually refers to eyelid abnormalities, orbital deformities, motility disturbances, or redness of the eyeball.

Visual Acuity

An eye examination begins with determining the visual acuity of each eye, with the other eye completely covered. Although measurements are obtained at a distance and near, with and without refraction (glasses), the most important determination of general eye condition is the best-corrected-distance visual acuity, usually assessed with a Snellen chart (which has been in clinical use for 150 years). Examination of children often requires pictures or individual E charts. Each line on the chart is meant to

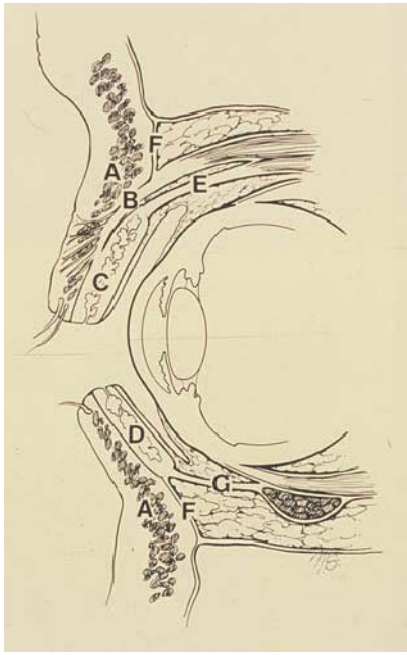

Figure 14.1 Cross-sectional anatomy of the orbital adnexae and globe: (*A*) orbicularis oculi muscles, (*B*) levator aponeurosis, (*C*) upper tarsal plate, (*D*) lower tarsal plate, (*E*) Mueller muscle, (*F*) orbital septum, and (*G*) lower eyelid retractors. be read by a person with normal vision at 20 feet (6 m). The largest letter should be seen at 200 feet (60 m) by a person with normal vision. If a patient can see that letter at a distance of 20 feet and is unable to see any of the smaller letters, vision is 20/200. If the line read by a person with normal sight can be seen at 20 feet, and the patient is 20 feet from the chart, the vision is 20/20. If the patient is unable to read the largest letter on the chart, the distance at which he or she can count fingers accurately is recorded. If the patient cannot count fingers, the distance at which hand movements are perceived is determined. If this is not possible, whether the patient can perceive light is documented. Table 14.1 compares visual acuity with visual ability or disability. Vision is not a true fraction. In other words, 20/40 vision does not mean 50% of normal vision but that the patient can see at 20 feet what a person with normal sight can see at 40 feet (12 m). If the patient can see the 20/20 line by wearing glasses, his or her functional vision is probably just as good as that of someone who sees the line without glasses.

The ophthalmologist uses the process of refraction to determine the refractive error of the eye or the lenses needed for the eye. The need for refraction is determined with a pinhole test. The patient views a chart through a 1-mm pinhole, which reduces the blur of the image on the retina and appreciably increases visual acuity if it is decreased owing to a refractive problem. This test helps to rule out retinal or optic nerve dysfunction as a cause of decreased vision. Measurement of best-corrected visual acuity is an important concept. Often, patients say they are "blind" without their glasses. They should be informed that vision can be physiologically abnormal without pathologic consequence.

Peripheral vision, or side vision, can be evaluated with visual field testing. This test can be performed with various instruments, but it is commonly performed with the confrontation technique. The patient is asked to fix on the examiner's nose with one eye and to cover the other eye. A test object or finger is brought in from the side until the patient reports it is being seen. The visual field is approximately 90 degrees on the same side but only 50 degrees on the opposite side of testing. Abnormalities of peripheral vision often are detected only through examination because patients report loss of central vision, but loss of peripheral vision is not easily detected. Performing this test for each eye is a good screening method for many neurologic diseases. Ophthalmologists will use a more sophisticated perimeter test to obtain a graphic representation of each visual field to identify and follow visual field defects.

External Inspection and Pupil Examination

Inspection of the external eye structures includes the eyelids, eyelashes, lacrimal apparatus, cornea, conjunctiva and sclera, anterior chamber, and iris, as well as the general symmetry of the face and orbits. Much information can be obtained with this examination, which often reveals the presumptive diagnosis. Particular notice should be taken of abnormal alignment of the eyelids (ptosis or lid retraction), the position of the eyelids against the globe (entropion or ectropion), and abnormal direction of the eyelashes (trichiasis). Swelling in the medial canthal area can indicate a block of proper lacrimal drainage. Proptosis always is an important finding (Fig. 14.2). The causative factor may be orbital, periorbital, or systemic disease. Specific abnormalities in the color and contour of the conjunctiva, cornea, and sclera are discussed later with "red eye." Of particular importance is an estimation of the depth of the anterior chamber in detecting an important form of glaucoma known as "angle-closure" glaucoma. This test can be performed with side illumination using a penlight. If the anterior chamber is of normal depth, the entire surface of the iris is illuminated. If the anterior chamber is shallow, the iris on the opposite side of the pupil is in shadow.

Examination of the iris usually centers on assessing the pupillary response. When light is shined into the eye, a normal pupil constricts and then redilates after the stimulus is removed. This is the *direct light reflex*. The opposite pupil constricts as well with the stimulus, and this is known as the *consensual light reflex*. These reflexes should be brisk and approximately equal. Pupillary constriction is also part of the "near-vision complex" associated with the process of accommodation. If the pupil

TABLE 14.1 CORRELATION OF VISUAL IMPAIRMENT WITH VISUAL DISABILITY

Visual Impairment	Visual Disability
20/12–20/25	Healthy young adults average better than 20/20 acuity Normal vision
20/30–20/70	Nearly normal vision Causes no serious problems but should be evaluated for potential improvement or possible early disease
20/80–20/160	Moderately low vision Strong reading glasses or magnifiers usually provide adequate reading speed.
20/200–20/400 or CF 10 feet (3 m)	Severely low vision (legal blindness in the United States) Gross orientation and mobility generally adequate but difficulty with traffic signs, bus numbers, etc. Reading requires high-power magnifiers. Reading speed and endurance reduced.
CF 8 ft (2.4 m) to CF 4 feet (1.2 m)	Profoundly low vision Increasing problems with visual orientation and mobility. Long cane useful to explore the environment. Highly motivated and persistent persons can read visually with extreme magnification. Others rely on nonvisual means: braille, talking books, radio.
<CF 4 feet (1.2 m)	Near blindness Vision unreliable except under ideal circumstances. Must rely on nonvisual aids
NLP	Total blindness. No light perception. Must rely on other senses entirely

CF, counts fingers; NLP, no light perception.

reacts to accommodation but not to light, it is the classic Argyll Robertson pupil, often associated with syphilis. A Marcus Gunn pupil is an important physical sign in the evaluation for neurologic disease. It is elicited with the swinging flashlight test. Light is shined in one pupil for 2 or 3 seconds and then rapidly swung back and forth between eyes. Prompt constriction should appear if each pupil is normal. If optic nerve disease or injury is present in the affected eye, the pupil gradually dilates, indicating a decreased direct light reflex. With an impaired neural connection in the affected eye, the examiner will observe a diminished pupillary response in both eyes when the normal eye is stimulated. Thus, the direct response to stimulation of the affected eye and the consensual response in the normal eye are both reduced, compared to the responses when the normal eye is similarly stimulated. Such a reaction usually indicates damage to the optic nerve via the afferent pupillary fibers. This sign is positive early in optic nerve disease, when vision still is 20/30 or better. Abnormal pupillary reaction in any form generally indicates a serious eye disease. For the otolaryngologist, normal visual acuity and normal pupillary responses are comforting findings in evaluating eye problems.

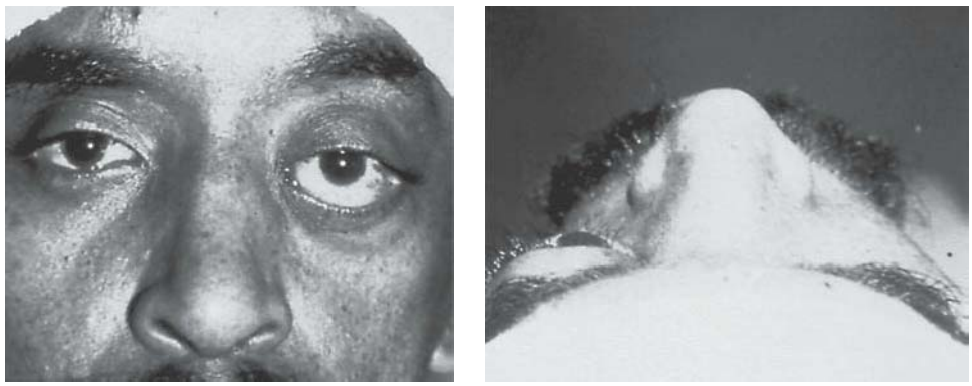

Figure 14.2 Proptosis of the left eye, viewed from anterior (**left**) and superior (**right**) positions.

Motility

Six muscles surrounding each eye are responsible for ocular motility. Several terms are used to describe various eye movements. The movement of one eye from one position to another is called *duction*. The simultaneous movement of both eyes from the primary, straight-ahead position to a secondary position (up, down, right, left) is called *version*. *Vergence* is the term applied to simultaneous rotation of both eyes inward (*convergence*) or outward (*divergence*). Evaluation of the extraocular muscle function is begun with general inspection to find any gross deviation of either eye (*heterotropia*). The patient is asked to look up, down, right, and left to reveal whether the deviation is the same in all fields of gaze (concomitant) or varies (nonconcomitant and usually neurologically significant) (Fig. 14.3). During these gaze movements, involuntary eye jerks, called *nystagmus*, may also be detected.

The flashlight used to evaluate pupillary reflexes also can be used to assess the corneal light reflex. The light should be symmetrically reflected in each pupil. If deviation is seen, the degree of abnormality can be estimated by the asymmetry of the light reflex in each pupil.

The cover test is used to evaluate motility. The patient is instructed to fix on an object. If both eyes appear straight (*orthotropia*), cover either one. If under cover the eye deviates, *phoria*, or latent deviation that becomes evident only when vision is interrupted, has been elicited. Usually, the eye resumes fixation when uncovered. If one eye is obviously deviated, the straight-ahead eye is covered. If the deviated eye rapidly moves to resume fixation, it most likely has good visual potential. The deviation can be eso (inward), exo (outward), hyper (upward), or hypo (downward). Motility disturbances may indicate congenital, neurologic, or metabolic abnormalities.

Figure 14.3 Heterotropia is characterized by gross asymmetry of eye movement.

Intraocular Pressure

Measurement of intraocular pressure (IOP) should be performed when assessing orbital trauma or before performing orbital, periorbital, or sinus surgery. The examiner can estimate IOP digitally by placing the tips of the index fingers on the patient's closed eyelids. All but gross abnormalities remain undetected when this technique is used. A tense globe might be appreciated on palpation as a firmness of the affected globe that is not present with the opposite globe. It is a "soft" sign but, if obvious, is a serious finding. Tonometry is the estimation of IOP with a specialized instrument. It can be performed with an indentation technique or an applanation technique. The former is used in the general screening process and is performed with a Schiotz tonometer. With the patient in a recumbent position, a drop of topical anesthetic is instilled into each eye. The patient is instructed to look straight ahead with both eyes open. Assistance in holding the eyelids open, with pressure on the orbital bones only, not the eye, may be needed. The plunger is gently placed on the center of the patient's cornea, and the corresponding scale reading is recorded. The test should require only 1 to 2 seconds of contact with the cornea. Normal IOP usually is 15 to 20 mm Hg, with an upper limit of 22 to 23 mm Hg. Both eyes should be tested, in order to obtain baseline levels in the "normal" eye and to compare the pressures between eyes, particularly after facial trauma.

Ophthalmoscopy

The final part of a pertinent eye examination is ophthalmoscopy. It is used to evaluate the internal structures of the eye, primarily the retina, retinal blood vessels, and optic nerve. A direct ophthalmoscope is used for this examination and provides an upright 3× magnified image. Great limitation of the field of view occurs, and the information is obtained as if the examiner is viewing through a small pupil. A 3-mm pupil gives only a 4-degree field of view, but a 7-mm pupil allows a 30-degree field of view. Therefore, routine dilation of the pupils with 0.5% or 1% tropicamide or 2.5% phenylephrine is recommended, with the following exceptions: known narrow-angle glaucoma, neurologic or neurosurgical observation, and some types of intraocular lens implants after cataract surgery. In rare instances, dilation of the pupil can precipitate an attack of acute angle-closure glaucoma that was previously unsuspected. This low risk should not be considered a contraindication to performing the examination. Because this form of glaucoma is rare and can be managed effectively, the benefits of improved ophthalmoscopy through dilated pupils outweigh the risks.

The examiner holds the ophthalmoscope in the right hand and uses the right eye to examine the patient's right eye. With the pupil dilated, reflected light from the ocular fundus produces a clear red reflex when viewed through

the ophthalmoscope with a 16 diopter lens at a distance of approximately 1 foot (0.3 m). Any alteration in the red reflex indicates abnormality in one of the optical structures of the eye and is always important. The patient's eye is then approached as closely as possible as the power of the lens in the ophthalmoscope is reduced until the optic disk comes into focus. The nerve head, at the back of the eye, should be evaluated for color, sharpness of margins, and appearance of the central depressed area, known as the *cup*. Systematic examination of the retinal vessels and background then is performed. The macular region deserves special attention for patients with vision loss. This examination is performed on both eyes.

Schirmer Testing

The Schirmer test is only a general qualitative screening test for tear production. It is often equivocal and only a glimpse of the tear production at the time of the test. Hydration status and environmental factors can change tear production even within a day's time. There are three components to the Schirmer testing, all three of which should be performed to gain as much information as possible.

The Schirmer I test can be performed with or without topical anesthesia (2). For all tests, the lower cul-de-sac is wiped clean of retained tears, gently, with a cotton-tipped applicator. For the unanesthetized test, the filter paper strip (Whatman filter paper no. 41) is notched and placed in the lower eyelid cul-de-sac and left in place for 5 minutes—the patient eyes can be open or closed. This test measures both basic tear production by the accessory tear glands as well as the reflex tearing from the lacrimal gland produced in response to the foreign body on the conjunctiva of the eyelid. A "wetting" of the paper of 10 mm or greater is considered "normal." The second part of the test is to apply two drops of 0.5% ophthalmic tetracaine solution to the inferior cul-de-sac, which eliminates the reflexive tear production by the lacrimal gland and measures the basic tear secretion by the accessory glands (i.e., meibomian glands). The test is then conducted similarly to the unanesthetized version. A paper "wetting" of less than 5 mm is considered abnormal. The third portion of the test is the Schirmer II test, which can be performed with the eyelid either anesthetized or unanesthetized. In this test, the ipsilateral nostril is stimulated with cotton from a cotton-tipped applicator to stimulate a neural reflex for tear production, similar to that which occurs naturally when a foreign body is inhaled into the nose. Any "wetting" under 15 mm is likely abnormal.

Quite a number of etiologies can explain inadequate tear production, including facial nerve dysfunction, advancing age, postmenopause, Sjogren disease and other autoimmune diseases, dehydration, and medications (antihypertensives, diuretics, birth control pills, psychotropics), just to name a few. The importance of Schirmer testing in otolaryngology–head and neck surgery is primarily in the preoperative assessment for eyelid surgery and in the diagnosis of autoimmune disorders affecting the head and neck region.

VISUAL ABNORMALITIES

Physiologically Decreased Vision

Refractive Error

A common cause of poor vision is refractive error or change in refractive error. Patients with *myopia* (nearsightedness) have an eye that is axially too long for its refractive system. Typically a young patient reports not being able to see the blackboard and having to sit at the front of the classroom. Simple prescription of concave lenses usually restores visual acuity to normal. Persons with *hyperopia*, or farsightedness, have an eye that is axially too short and need simple convex lenses to bring near objects into focus. *Aphakia* is a special form of hyperopia in which the refractive power of the eye is too weak following surgical removal of the lens. *Astigmatism* is the nonspheric curvature of the cornea and is extremely common with any refractive error.

Refractive visual surgery, in the form of LASIK (laser-assisted *in situ* keratomileusis) or PRK (photorefractive keratectomy), is becoming increasingly common among patients with myopia. Patients seeking elective reduction of physiologic myopia elect these procedures, which reshape the cornea to improve its curvature. New technology can produce a detailed topographic "map" of the corneal surface, which drives the reshaping process very precisely. These advances have reduced complications and produced more consistent results, including a decreased trend toward a hyperopic drift with time. Some patients need additional mild corrections after the primary surgery, called *enhancements*, to complete the visual improvement process. Side effects of corneal reshaping surgery include halo effect, double vision ("ghosting"), loss of contrast sensitivity, and glare.

Presbyopia

Presbyopia is the term used to describe the clinical need for reading glasses or bifocals as the patient enters the fourth and fifth decades of life. The crystalline lens hardens with age and becomes less elastic, decreasing ability to accommodate or focus for near vision. This is a normal physiologic mechanism and should not be considered a sign of disease. When a cataract forms and interferes with functional vision, it can be removed and replaced with a synthetic, polymer lens specific to the patient's vision system.

Pathologically Decreased Vision

Gradual Loss of Vision

In evaluating reduced vision in pathologic terms, best-corrected visual acuity must first be achieved to eliminate the physiologic abnormalities. The three most common causes of gradual loss of vision are cataract, senile macular degeneration, and glaucoma.

Cataract formation, the loss of transparency of the crystalline lens, is common. Increased density of the lens fibers

and changes in protein content occur, almost without exception, to some degree in every person with increasing age; however, the loss of transparency can be so marked that visual function is seriously hampered. The term *cataract* usually is reserved for the latter situation. Cataract formation usually is evolutional, but it occasionally has a specific cause, such as galactosemia, galactokinase deficiency, diabetic ketoacidosis, postradiation therapy, or trauma. If a metabolic abnormality can be corrected early in the course of cataract formation, some lens opacity can be reversed; however, there is no known reversal of lens changes due to senile cataract. Treatment is surgical removal of the cataract. The need for surgery usually depends on the patient's visual requirements and desires. In rare instances, the cataract damages the eye because of high pressure from rapid swelling and may have to be removed for other than optical reasons.

The operation usually is performed by means of opening the anterior capsule and extracting the lens material. The posterior capsule is left intact and the lens substance removed by *phacoemulsification*. After a person is *aphakic*, the optical power of the lens must be replaced to provide focusing ability. The patient can be fitted with spectacles or contact lenses after the eye has healed, but usually, a polymer intraocular lens is implanted during the surgical procedure, with the appropriate lens strength being determined preoperatively. It is comforting to inform patients that cataract surgery is one of the most successful operations performed.

A second important cause of gradual progressive decrease in vision among older persons is *senile macular degeneration*. The cause of this condition is unknown, but it may be related to a decrease in the blood supply to the macular area associated with hardening of the arteries in the posterior eye, which begins as a pigmentary disturbance in the macula and usually progresses slowly but steadily with increased scarring and often hemorrhage into the tissues. The disease is bilateral but usually asymmetrical. No effective treatment exists, and normal use of the eyes, as for sewing and reading, does not accelerate the process. Patients should be assured that macular degeneration is not a blinding disease because the peripheral vision is not disturbed. Patients with this condition always are able to move around unaided, even though their useful reading vision may be markedly decreased.

Unlike the two aforementioned visually disabling conditions, glaucoma characteristically produces a decrease in peripheral visual ability, but good reading vision is maintained until late in the disease. Mild glaucoma can normally be controlled with daily topical eye drops.

Sudden Loss of Vision

Sudden loss of vision is a dramatic event and usually is caused by an identifiable pathologic process. Some processes can be treated and controlled to allow restoration of vision, while others produce permanent loss of visual function. Vitreous hemorrhage unrelated to trauma can occur in advanced diabetes mellitus as a result of disease of the retinal blood vessels. The vitreous "haze" prevents complete examination of the retinal blood vessels, and the offending area often remains unidentified until the blood is reabsorbed. It can take months or years for the vitreous to clear in a relatively young person, producing marked disability, while it may never clear in an older person.

Central retinal arterial occlusion causes total and permanent loss of vision and abolishment of the direct pupillary reaction to light. On ophthalmoscopic examination, the fundus will appear pale with development of a cherry-red spot in the macula. The spot is caused by continued choroidal blood supply to the macula with the contrasting loss of circulation to the rest of the retina. The retinal arteries are narrow and may have fragmented blood columns ("boxcar sign"). The cause usually is an embolus from diseased carotid arteries, abnormal heart valves, or thrombosis from long-standing atherosclerosis. In rare instances, central retinal arterial occlusion is a vasospastic event associated with an inflammatory disease. Treatment aimed at relieving the obstruction through drug-induced vasodilation, ocular massage, and inhalation of 5% carbon dioxide and 95% oxygen usually is unsuccessful. Attacks of *amaurosis fugax* and central or branch retinal artery occlusion have been shown to be related to internal carotid artery stenosis (3). An increase in ulcerated free plaque surfaces appears, which might lead to arterial embolization. Duplex ultrasonography and continuous-wave Doppler ultrasonography can be used for obtaining a noninvasive diagnosis; however, magnetic resonance angiography (MRA) is rapidly gaining favor as a sensitive screening test for carotid stenosis.

Central retinal venous occlusion is more common and less dramatic than arterial occlusion, and it has a markedly better prognosis. On ophthalmoscopic examination, the fundus has a dramatic appearance, as if the entire view has been splattered with blood, and the observed vessels appear engorged and tortuous. Much of the hemorrhage clears with time, vision returns, and late complications of retinal anoxia are managed by the ophthalmologist.

Retinal detachment is not a rare occurrence. It is much more common among persons with high myopia (those with long eyeballs), after cataract surgery (~1 in 100), and following facial trauma. The mode of visual loss varies. The patient commonly reports a shadow or curtain in front of the eye, ascending or descending, depending on the direction of the spreading separation of the retina. Associated flashing lights and floaters may be seen as the retinal structure is disturbed. If the macula becomes detached, central vision is abruptly lost. At ophthalmoscopy, the detached retina is found to be pale and wrinkled and to project forward into the vitreous, often to the point at which objects viewed cannot be focused by the lens onto the retina. Surgical reattachment of the retina is successful in 60% to 80% of cases, but return of vision depends on early

Figure 14.4 Edema of the optic disk indicates optic neuritis.

diagnosis, length of time detached, and avoidance of late surgical complications.

Optic nerve compromise, whether in the form of ischemia or inflammation, is not as common as retinal detachment, but it is equally dramatic and important. A patient older than 55 years who has sudden loss of vision and perhaps has vague arthritic symptoms, low-grade fever, or temporal scalp tenderness should have the erythrocyte sedimentation rate (ESR) measured. If the ESR is elevated, the diagnosis is most likely *temporal arteritis*, with the opposite eye being at risk for parallel visual loss. Systemic steroid therapy should be initiated early to prevent the onset of inflammation in the other eye. For a younger person, if loss of vision is associated with edema of the optic disk, the diagnosis is likely *optic neuritis* (Fig. 14.4). The prognosis for return of vision is good, but the possibility that a demyelinating disorder, such as multiple sclerosis, is present must be strongly considered.

Sometimes, the report of sudden loss of vision is unfounded. This usually occurs when an older patient suddenly "discovers" a loss of sight that has existed for some time. Chance occlusion of the seeing eye reveals the visual loss, which is erroneously reported as being acute. The report of sudden loss of vision also can be associated with hysteria or malingering and the desire for secondary gain. This is especially true in young adolescents.

Transient Loss of Vision

Transient loss of vision can be part of the aura of migraine or a consequence of chronic papilledema. Visual blackouts are common in vertebral–basilar insufficiency after at least 80% narrowing of this vascular system from atherosclerosis. These blackouts are ominous because repeated attacks often are not transient and can be permanent. Abnormalities in the carotid system can cause temporary, usually unilateral, loss of vision (*amaurosis fugax*). Associated cerebral symptoms and hemiparesis may be noted. Because 15% to 20% of these patients later have a stroke, they need a complete vascular evaluation.

Diplopia

Diplopia is another symptom of visual abnormality. Physiologic diplopia is a normal phenomenon in which objects not within the area of fixation are seen as double. This is easily seen when one looks at a near object with attention directed at a distant object, which then appears double. Usually, this is not in one's conscious awareness. Diplopia can either be monocular or binocular, and this must be determined initially through eye cover testing (4). Pathologic diplopia is a cardinal sign of weakness of one or more of the extraocular muscles and usually is caused by neurologic disease, trauma, or diabetes mellitus. Diplopia also can occur with normal muscle function if the globe is displaced, as in slowly progressive e orbital disease or tumors that prevent proper alignment of visual stimuli. Monocular diplopia (that which does not go away when one eye is covered) is rare and usually due to splitting of light rays by an irregularity in the cornea, certain types of cataracts, or misaligned photoreceptors in the macula. More commonly, monocular diplopia is a neurotic or functional disorder.

RED EYE

The otolaryngologist–head and neck surgeon occasionally encounters a patient with a *red eye*, possibly in conjunction with another disease or after treatment. The condition causing the red eye often is a simple disorder, such as blepharitis or infectious conjunctivitis (viral), or a reaction to a surgical prep solution or postoperative topical antibiotic that is easily managed by the otolaryngologist if the proper diagnosis is made. In some instances, however, the condition causing a red eye is a more serious disorder, such as intraocular inflammation or acute glaucoma. A patient with one of these vision-threatening conditions requires the immediate attention of an ophthalmologist. The otolaryngologist must be able to differentiate minor irritation from a serious eye disease. Red eye can be caused by infection, inflammation, or allergic reaction of the eyelid, adnexal structures, or intraocular tissues. Other important causes are acute glaucoma, trauma, and various systemic diseases. If in doubt, refer the patient to an ophthalmologist.

Eyelid Abnormalities and Blepharitis

Many common disorders affect the eyelids. A sty (*hordeolum*) is an acute infection of one of the glands in the eyelid, similar to a boil or furuncle in other skin areas of the face. The patient typically has a red eyelid with moderate tenderness and swelling in the involved area. Associated redness

of the conjunctiva may be found. These lesions usually are self-limiting and drain spontaneously, or the patient can be treated with warm compresses and a short-term topical antibiotic such as azithromycin. A chronic lipogranulomatous structure known as a *chalazion* is caused by an abnormality in the meibomian glands of the eyelid. If the patient requests treatment (which is not usually urgent), this lesion can be improved by surgical curettage. Diffuse inflammation or infection of the eyelids is known as *blepharitis*. It characteristically has two forms. The first is a chronic staphylococcal infection of the glands surrounding the eyelashes. Abnormal oil secretions from these glands irritate the eye and cause redness and sometimes small, whitish infiltrates in the cornea near the limbus. The other form is *blepharitis* associated with typical seborrhea of the scalp, eyelashes, and eyebrows. These conditions tend to cause swelling of the eyelids, a moderate amount of erythema of the lid margins, and mild to moderate conjunctival injection. The patient describes having irritated eyes with scaling or crusting of the eyelashes. Treatment is long term and is directed at eradicating the contaminated flora, controlling the scalp seborrhea, and cleaning the lids with an ophthalmic lid scrub preparation. Anatomic abnormalities of the eyelids, such as entropion, with irritation due to misdirected eyelashes (*trichiasis*), or ectropion, which causes poor tear function and corneal exposure, can be eliminated as the cause of redness by simple observation.

Conjunctivitis, Episcleritis, and Scleritis

Conjunctivitis is inflammation of the mucous membrane covering the globe and lining the inner part of the eyelids. Conjunctivitis usually is infectious or allergic. Viral conjunctivitis caused by the adenovirus group is the common "pink eye" for which children are sent home from school as a public health preventive measure owing to a high transmission rate. Symptoms are mild, with only diffuse redness of the conjunctiva, minimal clear discharge, and perhaps a tender preauricular lymph node or associated pharyngitis. The condition is generally self-limited, but it is highly contagious in its early stages. Bacterial conjunctivitis is commonly caused by strains of *Staphylococcus*, *Diplococcus*, or *Haemophilus*. The patient has mild symptoms of "grittiness" and photophobia. The most characteristic finding is that the lids stick together overnight because of a mucopurulent discharge. If acute, copious purulence is present, the offending agent may be *Neisseria gonorrhoeae*, and further historical and systemic investigation should be performed. Routine culturing is recommended for documentation of infection, and a prompt response normally occurs to treatment with broad-spectrum topical antibiotics, such as a fluoroquinolone. If symptoms persist for more than 2 weeks, an alternative diagnosis should be entertained, or drug resistance suspected.

Allergic conjunctivitis can occur in response to topical medications, cosmetics, aerosols, or as part of an ocular–nasal hypersensitivity complex. The first exposure can be dramatic with severe itching and profuse watering associated with marked edema of the conjunctiva (*chemosis*). The eyelids may be swollen shut, similar to the allergic reaction to an insect sting. This condition can be unilateral or bilateral. It usually is managed with cold compresses and topical and systemic allergy therapy, with avoidance of the offending allergen, if possible.

Deep to the conjunctiva are the episcleral tissues and sclera. If the inflammation is not merely superficial, the patient will report a sensation of deep pain, and the erythema will appear dark red or purplish—*episcleritis* or *scleritis* should be considered. *Episcleritis* usually is an isolated patch of inflammation without significant sequelae. In contrast, more than 50% of cases of *scleritis* are associated with systemic disease, usually of a rheumatoid nature. A *pterygium* is a soft, fleshy growth of fibrovascular tissue from the conjunctiva that can later encroach upon the cornea. Usually, it is an innocuous disorder, which can be treated medically, unless the growth involves the visual axis over the pupil—at that point, surgical removal is needed. Recurrent inflammation of a *pterygium* can also produce a discrete area of conjunctivitis.

Keratitis

Keratitis is an inflammation of the cornea. Although often mild, this condition can be dangerous and threaten vision. Disruption of and infiltrates in the cornea always produce pain, photophobia, and decreased vision. The conjunctiva is injected, and iritis may be present. Keratitis caused by the herpes simplex virus is a concerning ocular condition. The infection typically forms a branching dendritic pattern on the cornea that can be readily seen on slit lamp examination. If recognized before corneal scarring occurs, the infection can be controlled with any of several antiviral medications. Long-term oral acyclovir use seems to remain effective in decreasing the number of ocular herpes simplex virus recurrences beyond 12 months (5). Iridocyclitis can be caused by the varicella-zoster virus, which affects the ciliary body and the skin of the tip of the nose along the nasociliary nerve.

Bacterial, viral, or fungal corneal ulcers are serious conditions that necessitate intensive therapy and cause prolonged morbidity. Ulcers caused by *Pseudomonas* organisms sometimes progress to perforation of the cornea within 24 to 48 hours despite intensive therapy. Because any disruption of the corneal epithelium can allow entrance of opportunistic organisms, infection must be considered, particularly after trauma and in the treatment of debilitated patients with a poor tear film. A topical ophthalmic antibiotic solution may be prescribed if bacterial superinfection is suspected or confirmed. A fluoroquinolone is usually prescribed. Topical steroids are not indicated in fungal and viral keratitis.

Iritis and Iridocyclitis

The iris and ciliary body anatomically constitute the anterior uveal tract. *Uveitis* is a general term that describes inflammation of the iris (*iritis*), ciliary body (*cyclitis*), or most commonly both (*iridocyclitis*). Acute iridocyclitis causes severe aching of the eye, intense photophobia, tearing, and in many instances, decreased vision. The redness usually is most evident around the limbus over the ciliary body ("ciliary flush"), unlike the diffuse redness of conjunctivitis. The pupil is constricted owing to direct irritation of the iris sphincter muscle, and the anterior chamber fluid is cloudy owing to the presence of inflammatory exudate and cells entering the aqueous fluid. Severe secondary glaucoma can occur if clumps of this debris block the filtration angle. In most acute cases of iritis not associated with severe corneal disease or trauma, the cause is unknown, but the condition may be associated with tuberculosis, sarcoidosis, ankylosing spondylitis, rheumatic diseases, gonorrhea, or Reiter syndrome.

The objective in managing iritis is suppressing inflammation and easing pain due to spasm in the ciliary body. This is achieved with topical steroids and a topical cycloplegic agent. Systemic analgesics often are needed. Varicella-zoster outbreaks can involve the iris and produce marked iridocyclitis. This appears to be more common with involvement of the external nasal nerve, a branch of the ethmoid nerve, which is related to the innervation of the iris. The herald sign of this disorder is a painful eye, usually red, which is associated with herpetic eruptions along the ipsilateral lower half of the nose. This is considered an urgent ophthalmologic condition and should be managed by an ophthalmologist. *Varicella-zoster ophthalmicus* is a frequent first manifestation of acquired immunodeficiency syndrome (AIDS) or human immunodeficiency virus infection (6). Acute retinal necrosis also may be present. Herpetic lesions of the face have the highest association with AIDS. An underlying immunodeficiency syndrome should be suspected and investigated when herpetic lesions involve the eye.

Figure 14.5 Proptosis, chemosis, and redness of left eye suggest serious orbital or cavernous sinus disease.

Miscellaneous Causes

Several other important pathologic processes must be considered in the differential diagnosis of red eye. If a history of trauma is known, a foreign body or abrasion must be considered. Patients with acute angle-closure glaucoma have severe pain, a cloudy cornea, a dilated and sluggish pupil, a marked decrease in vision, and an increase in IOP. *Dacryocystitis* (inflammation of the lacrimal sac) is characterized by painful swelling and erythema in the medial canthal area, which can cause systemic symptoms with fever and marked leukocytosis. Treatment consists of heat, antibiotics, and surgical drainage. Orbital cellulitis is a serious condition and can be life threatening among children and persons with suppressed immune function. If ocular motility is limited, attention must be given to monitoring pupillary reaction and observing optic nerve compression as an ominous sign of visual loss. A red eye associated with sudden proptosis is a sign of serious orbital or cavernous sinus disease (Fig. 14.5). Tables 14.2 and 14.3 summarize the signs and symptoms helpful in the differential diagnosis of red eye and the indications for referral.

TABLE 14.2 SYMPTOMS OF RED EYE

Symptoms	Referral	Acute Glaucoma	Acute Iridocyclitis	Keratitis	Bacterial Conjunctivitis	Viral Conjunctivitis	Allergic Conjunctivitis
Blurred vision	R	111	1–11	111	0	0	0
Pain	R	11–111	11	11	0	0	0
Photophobia	R	1	111	111	0	0	0
Halo	R	11	0	0	0	0	0
Exudation	0	0	0	0–111	111	11	1
Itching	0	0	0	0	0	0	11
Head cold, fever	0	0	0	0	0	0,11	0

TABLE 14.3 SIGNS OF RED EYE

Signs	Referral	Acute Glaucoma	Acute Iridocyclitis	Keratitis	Bacterial Conjunctivitis	Viral Conjunctivitis	Allergic Conjunctivitis
Ciliary flush	R	1	11	111	0	0	0
Conjunctival injection		11	11	11	111	11	1
Corneal haze	R	111	0	1–111	0	0,1	0
Pupil	R	Middilated nonreactive	Small, with or without irregularity	Normal or small	Normal	Normal	Normal
Anterior chamber depth	R	Shallow	Normal	Normal	Normal	Normal	Normal
IOP	R	High	Usually low	Normal	Normal	Normal	Normal
Discharge		0	0	6	11 or 111	11	1
Preauricular node		0	0	0	0	1	0

R, referred to ophthalmologist; 0, absent; 6, present or absent; 1, mild; 11, moderate; 111, marked.

Guidelines for Treatment

Adult patients with bacterial conjunctivitis are treated with antibiotic drops rather than ointment, except at bedtime. Children are treated with ointment. A 10% to 15% solution of sodium sulfacetamide given four times daily for 4 days is recommended unless the patient has a sulfa allergy. Patients with sulfa allergies can be treated with tobramycin or gentamicin sulfate, or another topical solution may be substituted. Neomycin topicals are to be avoided because of the high incidence of allergic reaction and contact dermatitis. Cycloplegic eye drops, such as atropine, homatropine, or cyclopentolate hydrochloride, are used to reduce ciliary spasm to decrease pain. If these agents are prescribed, the patient must be warned of the side effects of decreased near vision and pupillary dilation. Topical anesthetic drops should be used for diagnosis only. Prolonged use can slow corneal healing and cause severe allergic reactions. Because these agents eliminate corneal sensation, the protective blink reflex is retarded, opening the pathway to corneal dehydration and injury.

Administration of topical steroids should be reserved for the ophthalmologist. If the condition is one best managed with steroids, the patient should be examined and treated by this specialist. Steroid eye drops make the patient feel better, but in conditions such as herpes simplex, keratitis, or fungal corneal ulcers, symptoms may decrease while the cornea is melting away and threatened by perforation. Several weeks of use of glucocorticoids can cause cataracts and elevation in IOP, which leads to typical glaucomatous optic nerve damage and visual loss.

Proptosis

Proptosis is a disconcerting presentation, both for the patient and the physician. The most common cause of proptosis is thyroid eye disease. Also to be considered are an expanding intraorbital mass, benign or malignant sinus disease, sphenoid ridge meningioma, and *idiopathic orbital inflammatory syndrome* (IOIS), also known as *orbital pseudotumor*. This condition of IOIS has no known cause and can affect any structure in the orbit. Its presentation may be insidious or abrupt (7). Typically, the diagnosis is one of exclusion and may be confirmed by a trial of oral steroids. If improved, then the steroid therapy may be continued until the condition has regressed. Occasionally, IOIS can be somewhat steroid-resistant, and low dose radiation therapy may need to be considered, weighing the risks and benefits. Both magnetic resonance imaging (MRI) and computed tomography (CT) scanning may be required to rule out other causes of proptosis.

OCULAR TRAUMA

When a patient sustains ocular trauma, the most important task is to differentiate a serious, potentially blinding problem from less serious problems. The care rendered by the first physician to examine a patient with ocular trauma frequently determines the visual outcome. A few minutes can make the difference between saving or losing sight. For these reasons, all patients with ocular symptoms should be treated according to an organized and evidence-based therapeutic plan. Posttraumatic (direct facial trauma) visual loss has a reported incidence ranging between 0.8% and 30% (8,9). Damage to the optic nerve, its tract, and projections in the brain are also causes of visual loss in the head trauma patient (10).

History and Examination

As in all specialties of medicine, a patient's symptoms and history provide clues about what the examination may reveal. A tearing or scratchy sensation usually is trivial,

but a chemical burn or penetrating injury can be visually devastating. The physician should always be cautious of a missed diagnosis. A trivial or seemingly minor injury can be accompanied by a small perforation of the globe or penetration of a minute foreign body into the eye. The likelihood of perforation should always be borne in mind during examinations, regardless of how minor the injury may appear. After the most careful examination, if the slightest doubt exists about the presence of perforation, prompt referral to an ophthalmologist is recommended and is usually the standard of care in a community.

A detailed history, as would be appropriate in outpatient care or in evaluating a chronic problem, is not indicated or necessary in an emergency. A focused, pertinent history is important, however. How did the trauma happen? For example, did something blow into the eye while the patient was walking outside, or was the patient grinding steel and struck in the eye by a piece of metal? When did the trauma happen? The chronology of events is extremely important. Also essential is a history of the eye. When a patient has a decrease in visual acuity, it is important to know whether that eye has had poor vision in the past or this is an acute change. Old trauma must be differentiated from the effects of a new injury.

After a history is obtained, a careful, focused examination of the structures involved should be undertaken, especially with documentation of visual acuity. This baseline is important from a medical legal point of view, and it is very helpful in ascertaining the extent of the injury and the progress of treatment. If a patient does not have his or her glasses for the examination because they were broken in the trauma, a pinhole test can be used to evaluate vision by obtaining the best possible acuity of the eyes.

Orbital Trauma

Trauma to the orbit can be superficial, resulting in only ecchymosis of the lid (black eye), or it can be extensive, involving the bony walls and intraocular structures. Knowledge of the orbital anatomy and its visualization on imaging studies, as well as indications for surgery, is very important for the otolaryngologist who cares for facial trauma patients (11). Plain radiographs of the orbits are of limited value after orbital trauma except for localizing embedded metallic foreign bodies. CT, both axial and coronal, provides the best information about osseous components of trauma. Soft tissue window algorithms can be used to assess hematoma formation, orbital fat prolapse, and other damage. Evidence of orbital emphysema on CT scan usually represents a loss of integrity of orbital walls. Although the air usually resorbs spontaneously, increased IOP and retinal artery compression can occur if extensive air is present due to volume expansion around the eye. Evaluation of extraocular muscle function can indicate intraorbital soft tissue entrapment in an orbital floor fracture. Subcutaneous emphysema in the eyelids can point to a medial wall fracture into the ethmoid air cells. Visual acuity should always be documented, as a decrease may indicate concomitant ocular damage. More than 30% of injuries to the bony orbit are associated with intraocular injury (12,13). If the injury is superficial or if the findings at radiography, motility studies, visual acuity testing, and globe inspection are normal, the patient can be reassured. Otherwise, a referral to an ophthalmologist should be made for further ocular examination and appropriate therapy.

Eyelid Laceration

Trauma to the eyelid can be routine or quite involved. A superficial laceration, parallel to the lid margin, is similar to a skin laceration in other parts of the body and can be repaired in the same manner. Foreign bodies, however, can be overlooked; therefore, the wound should be explored and irrigated gently before surgical closure. If deeper structures are involved, the anatomic relations of the levator palpebrae muscle, tarsal plates, and orbital septum must be identified, and the appropriate repairs performed if disrupted. Lacerations that involve the lid margin or are medial to the punctum and involve the canalicular structures require detailed surgical reconstruction. The primary repair is extremely important because secondary scar revision and attempts to reestablish the function of a scarred eyelid or tear-drainage apparatus are difficult. Faulty primary repair, through failure to suture the tarsus well and removal of marginal sutures too soon, can produce a notch in the eyelid that interferes with its ability to spread the tear film as well as causing epiphora. Irritation and constant tearing can be caused by loss of corneal epithelium as well as ulceration of the cornea. Complicated lacerations therefore should be managed by a surgeon knowledgeable in the anatomic and physiologic characteristics of the eyelids and associated structures.

Superficial Injuries of the Cornea and Conjunctiva

The eyelid and attached conjunctiva, although important, are considered superficial eye structures, and injuries to them often can be managed by a nonophthalmologist. Subconjunctival hemorrhage usually is without sequelae, behaving as a bruise elsewhere on the body. The patient should be reassured that the blood clears over a 10- to 20-day period. The hemorrhages can be caused by minor trauma or by coughing or sneezing; they also can occur spontaneously. Little or no value is seen in performing hematologic or blood coagulation studies for patients with spontaneous subconjunctival hemorrhages unless a history of frequent recurrence or other easy bleeding is given. In those cases, the possibility of blood dyscrasia should be considered, although most commonly the patient is noted to be on aspirin or other blood-thinning therapy. These

patients have a bright red eye, normal vision, and no pain. If subconjunctival hemorrhage is seen in conjunction with severe trauma, the otolaryngologist and ophthalmologist always must rule out more serious injuries to the deeper ocular structures.

Corneal or conjunctival foreign bodies first should be approached with irrigation. If this is not successful, they can be brushed out very gently with a cotton-tipped applicator or nudged out with a small pick or needle. One drop of topical anesthetic solution usually is all that is necessary to allow manipulation of the object. If a foreign body is not seen on ophthalmoscopic examination, but the symptoms or history indicate the presence of one, fluorescein stain can be used to outline a corneal abrasion. A small strip of fluorescein paper is moistened with sterile water, and this strip is applied to the inferior cul-de-sac while the patient looks up or to the superior cul-de-sac while the patient looks down. When a cobalt blue penlight or Wood lamp (ultraviolet light) is used, fluorescence may outline the abrasion. If the patient wears soft contact lenses, use of fluorescein should be avoided, because the dye can permanently stain the lenses. The pain of corneal abrasion is sharp and stabbing and is aggravated when the patient opens and closes his or her eyes. It is often associated with marked photophobia, unlike the deep ache of iritis and the superficial mild and intermittent discomfort of conjunctivitis.

If the abrasion is vertical over the cornea, the lid should be everted, and a foreign body may be found embedded in the conjunctiva of the upper lid. To perform lid eversion, the patient looks down while a cotton-tipped applicator handle, pencil eraser, or finger is placed just beneath the orbital rim. The eyelashes are grasped with the other hand and pulled straight out from the globe; the lashes are then pulled up and forward, and the eyelid flipped over the applicator stick or the base of the finger as a fulcrum. The everted lid is held against the orbital margin, and the underlying structures are examined. Approaching the patient with confidence makes this procedure simple.

Overwearing contact lenses or excess exposure to an ultraviolet sunlamp can cause severe punctate corneal damage with eyelid edema. Treatment usually is observational with symptomatic relief. Symptoms appear 6 to 12 hours after exposure or after the contact lenses are taken out. The patients experience marked light sensitivity and a feeling of sand or grit in the eyes. Superficial pain can be severe. Marked spasm of the lids is seen with associated tearing. It is not appropriate to use topical anesthetic eye drops to alleviate the mild and transient discomfort. Oral analgesics will provide adequate pain relief.

Misplacement of a contact lens is a common occurrence with patients. The lens usually can be found, with adequate evaluation, in the deep folds of the conjunctival fornices. The patient should be reminded that if it is not found, the lens did not migrate posteriorly into the intracranial structures but rather dropped out. This reassurance can only be rendered after a thorough examination.

Figure 14.6 Appearance of an injured eye with a corneal abrasion outlined with fluorescein dye.

Therapy for corneal abrasions, including treatment after removal of a foreign body, consists of antibiotic eye drops. This is recommended particularly if the injury was caused by contaminated material, such as a fingernail or a twig. If a large abrasion is present and the eye is quite inflamed, a cycloplegic agent can be used to reduce ciliary spasm and pain (Fig. 14.6). The eye often is patched for comfort for 24 hours to speed healing. Topical steroid or steroid–antibiotic eye drops should *not* be prescribed, and topical anesthetics should not be given for home use. Most small abrasions heal spontaneously within 24 to 48 hours and larger ones in less than a week.

Blunt Trauma

A severe blow to the eye or orbit can miraculously spare the ocular structures, or it can be devastating to them. The most common physical finding in cases of blunt trauma is *hyphema* (blood in the anterior chamber). If an eye has sustained a blow hard enough to cause ciliary body bleeding, which is believed to be the origin of the blood, the anterior chamber angle structures can be anatomically and physiologically disrupted and the filtration network compromised. The patient is at risk for development of increased IOP, either acutely or at a later time. Dislocated or subluxed cataractous lenses may also occur from blunt trauma to the orbit and eye. The vitreous can be detached and become hemorrhagic, and retinal holes or detachment may occur, leading to visual loss. Scleral rupture can occur anteriorly or posteriorly, and the optic nerve can be contused or avulsed. Blunt trauma to the eye necessitates a rapid and complete ophthalmologic examination with lifelong care and follow-up evaluations for significant injuries to the eye.

Penetrating Injuries

If the eye has been penetrated, urgent care must be administered by an ophthalmologist. If the otolaryngologist

suspects a penetrating eye injury, the eye should be protected and an immediate consultation requested. If foreign bodies are partially extruding from the eye, the diagnosis is evident. The foreign body should be left intact and removed in the controlled environment of an operating room. A key to the diagnosis of penetrating eye trauma is the appearance of a "peaked" or "teardrop" pupil. If the pupil is not round and is pulled to one side, the examiner should suspect a penetrating injury and treat the affected eye with extreme care, with no further manipulation of the orbit. The combination of lid laceration and hyphema also suggests penetration. To transport a patient with a penetration wound of the eye, an aluminum shield or a cone made from x-ray film, or a plastic drinking cup, can be placed over the involved eye to avoid pressure that can cause extrusion of intraocular contents. Tetanus prophylaxis is appropriate, especially if the etiology is unknown or was a potentially contaminated object.

Burns

An emergency that often comes to medical attention too late is a chemical injury, owing to the very short time that elapses before permanent damage is done to the eye. Serious alkali or acid burns are true emergencies. In the first few minutes after injury, the toxic solution must be diluted with any liquid available. It is not necessary to spend time attempting to neutralize the solution—immediate and profuse dilution is extremely important. Copious irrigation should be performed for at least 5 minutes; the eyelids should be held forcefully apart during irrigation. The patient can also be held over a drinking fountain or under a low pressure water faucet for irrigation. Topical anesthetic usually is needed to remove particulate chemical matter from the eye. If lid spasm is severe, a selective facial nerve block of the orbicular muscles lateral to the orbit (using a short-acting anesthetic agent such as lidocaine) may be considered to keep the eyelids open for irrigation. After the diagnosis is made and initial treatment completed, an additional 20 minutes of continuous irrigation with balanced salt solution or lactated (isotonic) Ringer solution as a continuous intravenous drip should be undertaken. Cycloplegic and antibiotic eye drops usually are administered, and a sterile eye patch is gently applied after all local therapy has been completed. Thermal or flash burns of the eye and eyelid are managed with the same general measures as other skin burns. The ocular sequelae of chemical burns can cause total blindness. Damage to the eyelids from chemical or thermal burns usually causes severe cosmetic disfigurement, permanent tearing, exposure keratitis, and corneal ulceration or perforation.

PEDIATRIC OPHTHALMOLOGY

As the study of childhood disease entails a distinct category of otolaryngology–head and neck surgery, problems of the pediatric eye should be considered separately.

Congenital Abnormalities

The ocular structures can be affected by developmental abnormalities and congenital anomaly syndromes. These range from minor cosmetic deformities to complete lack of any visual components. Congenital glaucoma is characterized by a large eye and marked photophobia. Childhood cataracts often are of known cause, such as a manifestation of congenital rubella or a consequence of an inborn error of metabolism. Any abnormality in the red reflex elicited through the ophthalmoscope during examination of a newborn should be cause for referral. The "cat's eye reflex," or white pupil, suggests many serious diseases, the most severe of which is the most common malignant intraocular tumor of children—retinoblastoma.

Strabismus

Most of the practice of pediatric ophthalmology centers on the care of patients with *strabismus* (failure of the two eyes to look at the same object) and *amblyopia*, an important preventable cause of vision loss. Strabismus is misalignment of the two eyes so that only one eye is directed at the specific object of regard. General ocular inspection may reveal gross deviation of one eye. The corneal light reflex provides an estimation of the amount of the deviation. The cover test can help detect almost every case of strabismus. A small amount of phoria is present among most patients with normal eyes and should not be cause for alarm.

All newborns should be examined for gross alignment of the eyes. Up to age 3 to 4 months, children often have uncoordinated eye movements and can temporarily manifest actual strabismus. An ophthalmologist should be consulted if occasional deviations persist beyond this age. Infants with constant deviations should be referred at any age, as soon as possible. The determination, by examination or history, that a deviation is intermittent is an important prognostic sign. Normal binocular vision can develop only with precise coordination of the two eyes. If the mental object of regard is seen by only one eye, and another object seen by the opposite eye, the brain suppresses the accessory image to avoid diplopia, thereby turning off the input from the deviating eye. If the eyes are straight at least part of the time (intermittent strabismus), or if the deviation alternates (first one eye assumes fixation and then the other), a chance exists for full development of visual potential with therapy.

Esotropia

Esodeviation is the most common type of strabismus, often manifesting itself soon after birth and occasionally necessitating surgery to straighten the eyes. Esodeviation also can appear in the 2nd or 3rd year of life and can be associated with an attempt to focus the eyes owing to marked refractive error, which often can be corrected with glasses alone.

Pseudostrabismus

Among children with large epicanthal folds, an appearance of esotropia can be quite marked, a condition called *pseudostrabismus*. When the folds flatten with age, the appearance changes, leading to the unfounded misconception that children outgrow strabismus.

Exotropia

Exodeviation is less common than *esotropia*. It usually occurs intermittently with fatigue, daydreaming, or when the child is in bright sunlight. Normally, after correct diagnosis, no treatment is required, save for reassurance. Long-term follow-up is recommended.

Amblyopia

Amblyopia is defined as unilateral defective vision, uncorrectable by glasses, in an otherwise normal eye. It occurs in about 5% of the young adult US population and is commonly known as a "lazy eye." Half of all patients with amblyopia will have or have had associated strabismus. Refractive amblyopia occurs when a marked difference exists in refractive errors of the two eyes. Like suppression to avoid diplopia in strabismus, the brain turns off the blurred image produced by the eye with the greater refractive error to obtain a clearer object of regard. Occlusion amblyopia occurs if opacities of the ocular media, such as ptosis, cataract, or macular lesions, prevent adequate sensory input. Retinoblastoma often manifests as esotropia due to macular involvement. All patients with strabismus need complete dilated ocular examinations.

Detection

Amblyopia, if detected early, often is curable. Treatment rarely is successful after age 9, and best results are obtained if the patient is treated before age 5. The key to this disease is early intervention. Prompt investigation is mandatory if a child has obvious strabismus. Even if the eyes appear straight during a routine pediatric examination, the examiner should observe how the child watches a light, follows a moving object, and reacts to having each eye covered alternately. If amblyopia exists, the patient probably will resent, vocally or through evasive movement, covering of the "good" eye. Even before a child can give a verbal response to visual acuity testing, he or she should be able to maintain central and steady fixation with each eye. By age 3, visual acuity can be measured with picture cards or single E charts. The examiner must be certain that only one eye at a time is participating in the test. Children always try to peek if the opposite eye is not properly occluded. Young children may not quite reach 20/20, but as long as both eyes are near that standard and equal, the parents can be reassured. Amblyopia may be present if a two-line difference is noted between the two eyes on a visual acuity chart or if best vision is only 20/30 to 20/40. Although amblyopia is a relatively minor visual impairment, many adults with a history of lazy eye have vision of only 20/200 or even less due to an unrecognized amblyopia in childhood.

Treatment

Therapy for amblyopia is based on the simple idea of forcing the child to use the affected eye. Proper spectacle correction is followed by patching the normally used eye. The duration of treatment is monitored by the ophthalmologist. After maximal amblyopic treatment, surgical correction of any residual strabismus is undertaken to prevent recurrence of the amblyopia and to improve cosmesis and minimize psychosocial problems. Early detection and prompt referral of patients with strabismus or amblyopia can be one of the most important contributions of a physician treating pediatric patients.

Suspected Child Abuse

Unfortunately, child abuse has become one of the leading causes of death in infancy. For those physicians who see pediatric patients in the emergency center, it is important to recognize the herald signs of child abuse ("shaken baby syndrome") and to notify child protective services when suspected. Retinal hemorrhage is a not uncommon feature of child abuse, seen in 32% of children being evaluated for abusive head trauma (14). It is a feature of this unfortunate condition that should be kept in mind.

THE EYE IN SYSTEMIC DISEASE

Neurologic Disease

The ocular manifestations of systemic disease always play an important role in general medicine. Neurologic and neurosurgical diagnoses often are made from eye examinations, and the disease course can be monitored with an ophthalmoscope because the eye is truly the "window to the brain." Finding a fixed, dilated pupil or Marcus Gunn pupil is important. Swelling of the optic disk or true papilledema is an important ophthalmoscopic finding, indicating increased intracranial pressure. A patient with papilledema usually has normal visual acuity, elevation of the disk with absence of the cup, blurred disk margins, venous engorgement, hyperemia of the disk, and hemorrhage and exudate around the disk. The presence or absence of venous pulsation is not a reliable sign. Inflammatory swelling of the optic disk (papillitis or optic neuritis), commonly a result of demyelinating disease, may appear ophthalmoscopically similar, but the patient reports markedly decreased vision due to direct nerve damage.

Optic atrophy, often described as an "aspirin disk," appears as a pale nerve head without normal capillaries on the surface. It is a nonspecific finding related to some form of optic nerve compromise. The presence of an atrophic nerve is sufficient to explain decreased visual acuity,

but it represents only a physical finding and is not sufficient to confirm a neurologic diagnosis. The cause of optic atrophy must be established from the history, further ophthalmoscopic or neurologic examination, and appropriate advanced imaging. Common causes of optic atrophy include optic sheath and sphenoid ridge meningiomas, temporal arteritis, multiple sclerosis (optic neuritis), stroke, and traumatic injury.

Thyroid-Associated Orbitopathy

Also known as Graves ophthalmopathy and thyroid orbitopathy, thyroid-associated orbitopathy (TAO) can raise both functional and cosmetic concerns. Although the cause of proptosis can be a primary or metastatic tumor, arteriovenous malformation, or carotid cavernous fistula, by far the most common cause of unilateral or bilateral proptosis is abnormal thyroid function. It has been reported that 90% of TAO are associated with hyperthyroidism, while the remaining 10% of patients are either euthyroid or hypothyroid (15). In classic Graves disease, the patient appears "bug-eyed" owing to exophthalmos and eyelid retraction (Fig. 14.7). Approximately 40% of patients with Graves thyroid disease will ultimately develop TAO (16). Ocular motility may be reduced because of infiltration of the muscles and periorbital tissues with an abnormal mucopolysaccharide substance. If the cornea becomes desiccated from exposure or if orbital pressure increases to the point at which papilledema or optic atrophy occurs, the thyroid condition is considered "malignant" and often necessitates immediate medical and surgical therapy. Surgical therapy may consist of orbital decompression, usually transnasal, endoscopic, with homografts implanted in the eyelids to extend the length of the tarsus and close the palpebral fissure for corneal protection. Results of thyroid tests may not correlate with the progress or severity of the eye findings, but combined evaluation and follow-up care with an endocrinologist are encouraged.

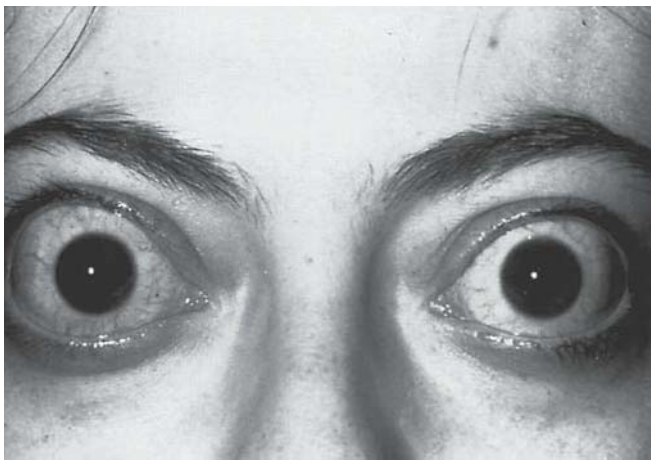

Figure 14.7 Exophthalmos and lid retraction due to Graves disease.

Collagen Vascular Disease

The external layers of the eye have a high collagen content. Inflammatory diseases that affect this tissue, such as rheumatoid arthritis or systemic lupus erythematosus, often cause external ocular inflammation. *Keratoconjunctivitis sicca* is the dry-eye component of Sjögren syndrome. Most of these diseases also have a vasculitis component, and retinal vascular sheathing and occlusions are common.

Systemic Infection and Metastatic Cancer

Systemic infection such as septicemia often establishes a metastatic focus in the eye, most commonly as choroiditis. Tuberculosis, syphilis, and histoplasmosis often are diagnosed in this manner. Orbital or elevated choroidal lesions often occur with metastatic carcinoma, especially metastasis from the lung and breast (Fig. 14.8).

Blood Dyscrasia

Blood dyscrasias, such as hyperviscosity syndromes, leukemia, or sickle cell disease, have characteristic retinal vascular patterns that may help confirm a diagnosis.

Ocular Side Effects of Medication

Ocular side effects, such as blurry vision and diplopia, are common side effects of many systemic medications. The increased IOP and cataractogenic effects of steroids have been mentioned. Ethambutol, chloroquine, and the phenothiazines are commonly used drugs with direct toxic effects on various ocular tissues. Patients taking these and other such medications need baseline examinations and periodic ophthalmic evaluation while on treatment.

Diabetes

Diabetes is associated with many eye changes, including transient changes in accommodation due to fluctuations

Figure 14.8 Orbital lesion due to metastatic carcinoma.

in blood glucose level, cataract formation, and the development of glaucoma. Retinopathy, however, makes diabetes the leading cause of blindness in the United States. Retinopathy is related to the duration and control of this metabolic disease. Within 15 to 20 years after the onset of diabetes, persons with juvenile- and adult-onset diabetes typically develop a visual disability. Good metabolic control can delay the onset of retinopathy, but it cannot totally retard the progression. Glycemia, hypertension, and abdominal obesity are determinants for retinopathy in a general population.

Diabetic retinopathy can be classified as nonproliferative or proliferative. *Nonproliferative* or "background" retinopathy consists of venous abnormalities, exudate, microaneurysms, dot-and-blot hemorrhage, and associated retinal edema. These are the earliest changes characteristic of diabetes, and they begin in the posterior pole of the eye, which is easily viewed with a direct ophthalmoscope. Patients with background retinopathy are generally not treated (unless macular edema is present) and can be observed with routine annual or biannual examinations. *Proliferative* retinopathy refers to the development of new, fragile blood vessels (neovascularization) in response to a hypoxia related to retinovascular disease. These vessels bleed into the retina, causing fibrosis and retraction of the retina to form a detachment, or bleed into the vitreous and cause sudden loss of vision through intravitreal fibrosis and traction on the retina. This end-stage diabetic disorder is called *retinitis proliferans*.

The current therapy for diabetic retinopathy includes vitrectomy and intraocular membrane stripping. After the onset of retinopathy, the 5-year survival rate for the retina is very low if left untreated. To prevent blindness, therapy is directed at the earliest sign of neovascularization. Laser photocoagulation, used to coagulate and destroy the hypoxic retina that is theoretically supplying the stimulus for neovascularization, produces the best long-term results for functional vision.

While retinopathy is the most well-known ocular disorder associated with diabetes, other ocular conditions can be associated with this metabolic disease (17). Cataract formation, *anterior ischemic optic neuropathy*, and *diabetic papillopathy* are conditions that not uncommonly occur with diabetes. Diabetes is also a risk factor for glaucoma, *ocular ischemic syndrome*, and possibly retinal vein and retinal artery occlusion. Patients with diabetes appear to also be more prone to corneal epithelial erosion or defects.

Hypertension and Arteriosclerosis

Hypertensive retinopathy and the retinal vascular changes of arteriosclerosis are quite characteristic. The term *arteriosclerosis*, not atherosclerosis, is better associated with changes in the retina. The central retinal artery usually divides into superior and inferior branches before it is visible on the optic disk; therefore, the vessels seen on ophthalmoscopy are arterioles. Diffuse narrowing of the retinal arterioles is the earliest sign of hypertension, which can be caused by the spasm of malignant hypertension of toxemia or renal disease and can be reversible if promptly treated. Hypertensive changes become permanent, however, if the pressure remains elevated for a prolonged period. Segmental arterial narrowing is the next progression, especially if the diastolic blood pressure remains at or greater than 120 mm Hg. Further damage to the vessel walls causes leakage of blood and plasma, forming superficial "flame-shaped" retinal hemorrhages, deeper dot-and-blot hemorrhages, hard and waxy exudates, and soft "cotton-wool" exudates (*retinal infarcts*). As a response to increased intracranial pressure or to anoxia of the optic nerve, papilledema develops. The 5-year mortality among patients with papilledema related to hypertension is greater than 90%. Large artery disease can also cause fluctuating visual loss, which may precede a cerebrovascular event (18).

Retinal arteriosclerotic damage revolves around changes in vessel wall transparency and abnormality in the arteriovenous crossings. Thickening of the arteriole wall increases in the light reflex stripe viewed through an ophthalmoscope. The thickening progresses until the light reflex appears to occupy the entire width of the blood column ("copper-wire" appearance) then progresses to the point at which no blood is visible at all, giving the characteristic white sclerotic "silver-wire" appearance. At points of arteriovenous crossing, the vessels are in a common adventitial sheath. As the arteriolar walls thicken, compression of the venules becomes apparent, first as tapering of the ends, progressing to "banking" with dilation of the venule distal to the crossing and finally to vascular occlusion with complete interruption of blood flow.

Separate categorization of these companion diseases can be important, even though in the advanced stages, almost without exception, the changes occur together. Specific hypertensive eye changes can alert the physician to the severity of the hypertension. More important, the arteriosclerotic changes mark the chronicity of the disease and mirror the condition of the vessels of the kidneys, heart, and brain. Elevated peripheral blood pressure should trigger a suspicion, leading to an ophthalmologic evaluation. Table 14.4 summarizes acute ophthalmic emergencies, including vascular disorders.

IMAGING IN OPHTHALMOLOGY

MRI is the most sensitive modality for evaluation of most disorders of the central nervous system, including stroke, white matter lesions, and hemorrhage; however, subarachnoid hemorrhage and acute stroke are better visualized with CT. CT imaging is the best imaging method for evaluation of orbital trauma. Within the orbit, MRI clearly is most effective for imaging the soft tissues, optic nerve, and retrobulbar space (19). MRA is an excellent screening tool for extracranial occlusive vascular disease, although it

TABLE 14.4 EMERGENCIES HYPERTENSION AND ARTERIOSCLEROSIS

Orbital burns
Extraocular muscle entrapment
Increased IOP after eye trauma
Proptosis after sinus surgery
Proptosis, chemosis, decreased motility, or decreased vision associated with sinusitis

slightly exaggerates stenotic lesions. If the carotid artery is found to be totally blocked at MRA, the patient probably cannot undergo surgical treatment. If intracranial aneurysm is suspected, however, conventional angiography remains the standard. MRI can be helpful in the diagnosis of craniopathy involving the orbit. For example, in third-nerve palsy, MRI can help identify brainstem infarcts, hemorrhage, and arteriovenous malformation; lymphoma and trauma involving the subarachnoid space; and cavernous sinus lesions such as cancer, aneurysm, and Tolosa-Hunt syndrome. The extent of periorbital sinus disease may be exaggerated with MR, so CT imaging may be considered as well.

High-resolution orbital A and B scans, 3-D ultrasound images, and ultrasonic color flow imaging can give important anatomic and histopathologic information about intraocular foreign bodies, masses, tumors, thyroid muscle disease, and vascular lesions.

OTHER OTOLARYNGOLOGIC-ASSOCIATED DISORDERS

Nonarteritic ischemic optic neuropathy (NAION) is a disease characterized by sudden visual loss that is painless and associated with nerve fiber bundle field defects, afferent pupillary defect, and optic disk edema. The onset most commonly occurs in the morning. NAION has recently been found to be associated with obstructive sleep apnea syndrome to a high degree (71%) (20). The damage is postulated to be due to impaired optic nerve head blood-flow autoregulation, secondary to repetitive prolonged apneas. Any acute visual disturbance in disturbed sleep patients warrants urgent ophthalmologic consultation.

Dry-eye syndrome is seen frequently in the older otolaryngology patient and is an important factor in surgery of the aging face or facial skin malignancy reconstruction. Incidence of dry eye is greater in older patients with a history of allergy or diabetes who use antihistamines or have generally poor health. Its incidence in the older population approaches 15% (21). Baseline evaluation using the Schirmer tear production test is a good starting point, but a formal ophthalmologic evaluation is recommended.

Significant precautions are to be taken by otolaryngologists in the use of lasers in the region of the face, head, and neck to prevent accidental eye injuries. Laser radiation can damage the eye by photomechanical, photothermal, or photochemical mechanisms. In otolaryngologic applications of the laser, thermal injuries are the most common, leading to protein coagulation. Retinal injuries can be most serious and are readily apparent ophthalmoscopically and angiographically. Retinal laser injuries do not cause chronic pain but can have disastrous visual consequences.

CONCLUSION

The clinical specialties of ophthalmology and otolaryngology–head and neck surgery have a great number of interfaces and overlaps, such that communication between the specialists in the care of patients with congenital, traumatic, neoplastic and inflammatory disorders. In particular, the perioperative evaluation of patients with disorders involving the orbit, globe, and adnexa benefits the otolaryngologist–head and neck surgeon in the diagnosis and management of potential complicating issues. The otolaryngologist–head and neck surgeon should freely consult the ophthalmologist and develop a collegial relationship, such that the patient will benefit from the collaboration. After all, it is always about the care of the patient.

HIGHLIGHTS

- If a person with normal sight is judged to see a certain-sized line at 20 feet (6 m) on an eye chart, a patient in comparison testing who can see that line at 20 feet is considered to have 20/20 vision. If the patient can see a line only at 20 feet that a person with normal sight sees at 200 feet (60 m), then the patient has 20/200 vision.
- A Marcus Gunn pupil is detected with the swinging flashlight test, in which light is shone in one pupil for 2 to 3 seconds and then rapidly switched to the other eye. A prompt constriction should appear in the normal eye, but with optic nerve damage or injury, the pupil gradually dilates.

- Sudden loss of vision can be caused by vitreous hemorrhage, central retinal arterial occlusion (which is irreversible), central retinal vein occlusion (which can be reversed in some cases), retinal detachment, optic nerve compression, or cerebrovascular accident.
- Physiologic diplopia occurs if an object in the near vision becomes double when gaze is focused on a far object.
- Pathologic diplopia occurs when objects appear in the direct fixation of gaze. It can be caused by neurologic disease, tumor, trauma, or a metabolic abnormality.
- Viral conjunctivitis as a cause of red eye is almost invariably associated with pharyngitis and an ipsilaterally enlarged preauricular node. It is highly contagious in its early stages.
- A patient with varicella-zoster skin eruptions on the tip of the nose also may have iridocyclitis because the ciliary body and the nasal skin are innervated by the same nerve.
- Topical anesthetic drops to the eye should be used only for diagnostic purposes. Prolonged use can retard corneal healing, cause severe allergic reactions, and, by eliminating corneal sensation, reduce the protective blink reflex.
- A horizontal laceration of the upper eyelid suggests injury to the levator muscle. Because a foreign body penetrating the eyelids also may have penetrated the globe, ophthalmologic consultation is mandatory.
- When vertical abrasion of the cornea is seen, it is likely that a foreign body is trapped in the upper eyelid. The eyelid should be completely everted and the conjunctiva closely examined.
- Chemical burns of the eyeball and eyelids should be continuously irrigated with Ringer lactate or balanced salt solution for at least 20 minutes, usually under local anesthesia.
- Retinopathy, in the form of retinal hemorrhages or tears, may be a sign of child abuse or "shaken baby" syndrome.

Anesthesiology

15

Stewart J. Lustik *Shawn D. Newlands*

Anesthetizing a patient for head and neck surgery is one of the most challenging aspects of anesthesia practice, which includes inducing the anesthetic state (amnesia, hypnosis, and immobility), airway and fluid management, and monitoring of cardiac and respiratory function. Patients scheduled for such surgical procedures frequently have partial upper airway obstruction or impending decompensation. The urgency of the operation, comorbidities of the patient, and the stability of the airway guide the selection of the anesthetic technique, particularly the maneuvers needed to secure the airway. Successful surgical and anesthetic care are intertwined; therefore, continuous, thoughtful communication between the surgeon and anesthesiologist is paramount, and understanding the basic principles, physiology, and pharmacology of anesthetic care is crucial to the success of the otolaryngologist.

Anesthesia is administered in numerous ways. General anesthesia renders the patient unconscious using a combination of drugs, and regional anesthesia blocks conduction of painful stimuli at the neuronal level. The latter technique involves infiltration of a local anesthetic around the surgical site; peripheral nerves; major nerves, such as the brachial plexus; or spinal cord (spinal, epidural, or caudal block). Infiltration of major nerves or the spinal cord is rarely used in head and neck surgery.

LOCAL ANESTHESIA

Local Anesthetic Agents

Local anesthetic agents (Table 15.1) are weak bases that reversibly inhibit nerve conduction by crossing cell membranes and intracellularly blocking electrically excitable sodium channels. The cationic form of the local anesthetic does not readily cross the cell membrane; thus, tissue acidosis renders local anesthetic agents ineffective, and local anesthetics do not work well if injected into abscesses or areas of cellulitis. Local anesthetics are linear molecules constructed of a hydrocarbon chain separating a lipophilic end from a hydrophilic end. The lipophilic end contains a benzoic acid moiety, and the hydrophilic end contains a tertiary or quaternary amine group. Anesthetics are subdivided based on the type of linkage between the benzoic acid moiety and the hydrocarbon chain. Amide anesthetics (lidocaine, mepivacaine, bupivacaine, etidocaine, prilocaine, and ropivacaine) contain an aminoamide linkage, whereas an aminoester bond characterizes ester anesthetics (cocaine, tetracaine, procaine, chloroprocaine, and benzocaine). The potency of a local anesthetic is related to its lipid solubility. The onset of action is dependent on the relative concentration of un-ionized drug and may be hastened by adding bicarbonate. The duration of action is associated with the degree of protein binding and the local anesthetics peripheral vascular effects. Addition of epinephrine decreases systemic absorption, which increases the duration of the block and decreases the risk of local anesthetic toxicity.

For both classifications of local anesthetics, the type of bond dictates the site of metabolism and route of excretion. Hepatic microsomal enzyme systems degrade the amides into metabolites that possess varying degrees of anesthetic potency. This process can be inhibited in patients with hepatic disease or reduced hepatic blood flow due to congestive heart failure or drugs such as cimetidine or propranolol. Plasma pseudocholinesterase metabolizes the aminoester drugs. This process is more rapid than hepatic metabolism except in patients with a genetically abnormal plasma pseudocholinesterase. The liver produces pseudocholinesterase, so patients with liver dysfunction will also have decreased metabolism of ester local anesthetics.

Lidocaine is both a topical and injectable local anesthetic. A 4% solution is most effective for topical use, whereas 0.5% to 1% solution is effective for injection into soft tissues. To avoid lidocaine toxicity, the recommended safe dosage is 4.5 mg/kg without epinephrine and 7 mg/kg

TABLE 15.1 LOCAL ANESTHETIC AGENTS

Drug	Physicochemical Characteristics	Route of Metabolism[a]	Route of Administration	Maximum Dose with and without Epi	Side Effects or Complications
Cocaine	Aminoester	Plasma cholinesterase	Topical	2 mg/kg 150 mg	Possible induction of allergic reaction by benzoic acid metabolite Vasoconstriction, possible induction of ventricular ectopy if used with halothane
Benzocaine	Aminoester	Plasma cholinesterase	Topical	3 mg/kg 200 mg	Methemoglobinemia at high doses
Tetracaine	Aminoester	Plasma cholinesterase	Topical	1.5 mg/kg	Seizures and myocardial depression at large doses
Lidocaine	Aminoamide	Liver	Infiltration	4.5–7 mg/kg (300–500 mg)	Seizures after rapid intravascular injection
Bupivacaine	Aminoamide	Liver	Infiltration	2.5–3 mg/kg (175–225 mg)	Cardiac arrest possible without previous seizures after rapid intravascular injection
Ropivacaine	Aminoamide	Liver	Infiltration	2–3 mg/kg (200–250 mg)	Seizures after rapid intravascular injection
Mepivacaine	Aminoamide	Liver	Infiltration	4.5–7 mg/kg (300–500 mg)	Seizures with overdosage

[a]Local infiltration assumed.

with epinephrine. Dilutions of 1:100,000 or 1:200,000 of epinephrine are commonly used with injected lidocaine. The lower dose is preferable to minimize the likelihood of side effects and has efficacy equivalent to that of the higher dose. Intravascular absorption of epinephrine may cause hypertension, tachycardia, and arrhythmias. The arrhythmogenic effects of epinephrine can be exaggerated by concurrent use of pancuronium or inhaled anesthetics, particularly halothane. Mepivacaine has an efficacy and toxicity profile similar to that of lidocaine, but mepivacaine has a longer duration of action. The remaining aminoamide local anesthetic agents are less commonly used during otolaryngologic surgery. Bupivacaine, because of its long duration of action, can be used for nerve blocks or infiltrated into wound closures to provide postoperative pain relief. The total dose of bupivacaine injected into the soft tissue of the head and neck should be limited to 2.5 mg/kg when injected alone and 3 mg/kg when mixed with epinephrine.

Cocaine is unique among the topical anesthetics because, in addition to being an excellent topical anesthetic, it is a potent vasoconstrictor. For this reason, cocaine can be used alone in the upper aerodigestive tract for both anesthesia and control of hemorrhage. Cocaine also is unique among local anesthetics in that it is highly addictive and thus one of the most abused drugs. Therefore, cocaine is limited in clinical practice to the mucous membranes of the head and neck. Combinations of lidocaine and epinephrine, phenylephrine, or oxymetazoline have been shown to be as efficacious as cocaine for a number of purposes (1), so many otolaryngologists avoid cocaine. Four percent cocaine has a rapid onset of action (5 to 10 minutes) with duration of action up to 6 hours. Cocaine inhibits the uptake of epinephrine and norepinephrine by adrenergic nerve endings; therefore, it potentiates the effects of catecholamines. The use of cocaine in conjunction with epinephrine risks cardiovascular complications that can prove fatal. The total dose of cocaine applied to the mucosa should be limited to 2 mg/kg. Severe or even fatal toxicity from cocaine can be caused by either central nervous system (CNS) or cardiovascular effects, including coronary artery spasm. Cocaine is metabolized by plasma pseudocholinesterase, and patients with this deficiency are sensitive to the effects of cocaine. Alternatives to cocaine should be highly considered in patients with coronary artery disease, poorly controlled hypertension, a history of arrhythmia, or thyrotoxicosis. Tetracaine is another excellent topical anesthetic agent, especially for ophthalmologic procedures. Although it has 10 times the potency of cocaine, tetracaine lacks the vasoconstrictor effect. Benzocaine, used as a topical spray, produces profound topical anesthesia but can cause methemoglobinemia if used in large doses. This drug is often used as a topical application to the upper aerodigestive tract before endoscopic procedures.

Local anesthetic systemic toxicity (LAST) involves the CNS and cardiovascular system. The signs of CNS toxicity occur early, with tinnitus, circumoral numbness, and agitation serving as early markers and seizures and unconsciousness indicating severe toxicity. The cardiovascular response can range from hypotension to ventricular

dysrhythmias and cardiovascular collapse. Treatment includes immediate management of the airway to prevent hypoxia and acidosis followed by midazolam if a seizure occurs. Advanced cardiac life support (ACLS) protocols should be followed for cardiac arrest, except the only antiarrhythmic considered should be amiodarone. A 20% lipid emulsion bolus (1.5 mL/kg) has proven beneficial, especially to treat bupivacaine, which tightly binds to cardiac sodium channels, resulting in prolonged cardiac arrest. Ropivacaine and levobupivacaine are newer agents, which have efficacy similar to that of bupivacaine but are less cardiac and cerebral toxic (2). Several steps should be taken to reduce the likelihood of LAST, including using the lowest effective dose of local anesthetic and aspirating before each 5-mL injection (3). Unfortunately, an adult patient's weight or BMI does not correlate with the plasma level after a dose of local anesthetic; thus, the maximum total dose in Table 15.1 should be observed. Acute allergic reactions are uncommon with amide local anesthetics, but may occur with esters, as they are broken down into *p*-aminobenzoic acid derivatives, a known allergen.

Nerve Blocks

In otolaryngology, local anesthetic techniques are used in procedures such as cosmetic facial surgery, in which distortion of tissue is undesirable. Thus, the goal is to infiltrate small volumes of local anesthetic around the peripheral nerve that supplies the surgical field with sensation. Sensory innervation of the head and neck is primarily from the trigeminal system and the cervical plexus. Effective blockade of sensory branches from these systems necessitates a thorough understanding of the anatomic features of the head and neck (4). This technique involves the use of a 25-gauge needle to infiltrate lidocaine or bupivacaine around sensory nerve branches as they exit the facial skeleton. It is important to avoid direct intravascular injection, as the unintentional injection of a local anesthetic into the vertebral or carotid artery can precipitate a seizure. Therefore, the practitioner should always aspirate before injection of local anesthetic to prevent complications.

Procedures on the face performed with local anesthesia should begin only after the branches of the fifth cranial nerve are blocked. Blocking the supraorbital and supratrochlear nerves with 1 to 3 mL of local anesthetic produces anesthesia of the forehead. The supraorbital nerve is found exiting the orbit in line with the pupil through the supraorbital notch, which can often be palpated. The supratrochlear nerve is approximately 1 cm more medial. Anesthesia of the external nose necessitates blocking the bilateral anterior ethmoidal nerves and infratrochlear nerves. This block is accomplished with either transcutaneous or submucosal injection at the junction of the upper lateral cartilage and the nasal bones laterally that extend superiorly between the medial canthus and the nasal dorsum.

The maxillary branch (V2) of the trigeminal nerve can be blocked in the pterygopalatine fossa with either a transoral approach or a transcutaneous approach, beginning at the coronoid notch and traversing the infratemporal fossa. This block anesthetizes the maxilla, palate, maxillary dentition, and the skin and mucosa of the midface. Procedures that necessitate such extensive anesthesia of the midface are more frequently performed with general anesthesia; therefore, this block is not commonly used. However, blockade of the major terminal branches of the maxillary nerve are common.

Infraorbital nerve block anesthetizes the maxillary incisors, cuspids and bicuspids, associated gingiva, lower eyelid, anterior cheek, and upper lip. Less than 3 mL of solution is necessary. The nerve, which is in line with the pupil and approximately 1 cm below the infraorbital rim, is reached with either an external or sublabial approach. The palate can be anesthetized by blocking the anterior palatine and nasopalatine nerves as they emerge from the greater palatine foramen and incisive canal. Small volumes (0.5 to 1 mL) of anesthetic are needed. During anesthetization of the infraorbital nerve, care must be taken, as injection into bony foramina can cause pressure-induced or needle-induced nerve injury and permanent paresthesia.

The mandibular branch of the trigeminal nerve can be anesthetized at the skull base as it leaves the foramen ovale. The needle is placed through the coronoid notch and across the infratemporal fossa. The injection is made posterior to the lateral pterygoid plate. Blockade of this nerve is used for procedures on the mandible, gingiva, lower teeth, lower lip, anterior two-thirds of the tongue, and floor of the mouth. Most procedures that necessitate this extent of anesthesia are performed with general anesthesia. Peripheral nerve blockade is more commonly applied to branches of the mandibular nerve.

The inferior alveolar nerve can be blocked through a transoral approach as the nerve enters the mandibular foramen in the pterygomandibular space. This technique is commonly used in oral surgery for work on the lower teeth. The injection is immediately medial to the mandibular ramus approximately 1 cm above the occlusal surface of the posterior molars at the anterior–posterior level of the coronoid notch. With this technique, the needle is superior to the medial pterygoid muscle and immediately medial to the mandibular sulcus. Use of this approach commonly blocks the lingual nerve because it is slightly medial and anterior to the inferior alveolar nerve. Anesthesia of the buccal mucosa is accomplished by means of blocking the buccal nerve as it passes over the anterior ramus at the level of the occlusal surface of the molars. Another commonly blocked branch of the cranial nerve V3 is the mental nerve. This blockade is accomplished with an injection at the mental foramen between the two bicuspids at a level immediately below the tooth root apices. The approach can be intraoral or extraoral. In edentulous patients, the location of the foramen can be found in line with the pupil. This technique anesthetizes the lower lip, gingiva, and teeth from the bicuspids to the midline.

Blockade of the cervical plexus anesthetizes the neck, inferior and posterior auricle, and scalp. The cervical plexus arises from the C2, C3, and C4 spinal nerves. These spinal nerves can be blocked as they emerge from the foramina in the cervical vertebrae with an approach lateral to the sternocleidomastoid muscle. This blockade must be performed with care to avoid intrathecal or intravascular injection into the vertebral artery. With injections of large volumes, involvement of the phrenic nerve is likely and thus should be used with caution in patients with respiratory compromise. This technique can be useful in complex surgical procedures on cervical structures, but these procedures usually are performed with general anesthesia. An alternative is to block the cutaneous innervation from the cervical plexus more safely by means of injection of up to 10 mL of local anesthetic at the posterior border of the midpoint of the sternocleidomastoid muscle (Erb point).

Blockade of the superior laryngeal nerve can be attained by means of infiltration of local anesthetic where the nerve enters the thyrohyoid membrane immediately inferior to the lesser cornu of the hyoid bone. This technique blocks sensory innervation from the epiglottis to the vocal cords and facilitates endoscopic procedures and awake fiberoptic intubations.

GENERAL ANESTHESIA

The unifying characteristics of general anesthetic agents are rendering a patient unconscious and insensible to painful surgical stimuli while controlling unwanted autonomic reflexes. The precise mechanism of action of anesthetics is unknown, although they all act by either positively modulating $GABA_A$ receptors (e.g., etomidate and propofol), inhibiting glutamate receptors (e.g., nitrous oxide and ketamine), or affecting both receptors (e.g., barbiturates and potent inhalational agents). The variety of available anesthetic agents enables the anesthesiologist to tailor care according to the demands of different surgical procedures and patients.

Inhalational Anesthetic Agents

The characteristics of common inhalational anesthetic agents are given in Table 15.2. These agents exist as liquids at ambient temperature and pressure and are transformed by a vaporizer into gas for rapid absorption and elimination by the pulmonary circulation. After absorption through the alveoli, the agents are distributed to the brain and spinal cord, where the anesthetic effects occur, as well as other tissues throughout the body. The concentration in the brain is directly related to the alveolar concentration. Alveolar and thus brain anesthetic partial pressure are increased by factors that increase anesthetic delivery (higher inhaled anesthetic concentration and alveolar ventilation) and decrease uptake (low solubility and alveolar–venous partial pressure differences). The potency of inhaled anesthetics is defined as the minimum alveolar concentration (MAC). MAC is the concentration that will prevent movement in 50% of patients to surgical incision and is additive between inhalational agents.

TABLE 15.2 INHALATIONAL ANESTHETIC AGENTS

Drug	Physical or Chemical Characteristics	MAC (%)	Excretion	Cardiovascular Effects	Respiratory Effects	Side Effects
Nitrous oxide	Supplied as a liquid in a pressurized cylinder	104	Lungs	Slight depression	Slight depression	Megaloblastic anemia Increase in intracavitary pressure in obstructed body cavities
Halothane	*N*-Alkane	0.76	Lungs Kidneys	Primary myocardial depression	Not a bronchoirritant Mild respiratory depression	Extremely rare cause of allergic hepatitis Triggering of malignant hyperthermia
Isoflurane	Ether bond	1.15	Lungs	Slight myocardial depression	Bronchoirritation Moderate respiratory depression	No major side effects
Desflurane	Ether bond	6.0	Lungs	Slight myocardial depression Sympathetic stimulation	Bronchoirritation Moderate respiratory depression	Coughing Laryngospasm
Sevoflurane	Ether bond	1.85	Lungs	Slight myocardial depression	Not a bronchoirritant Mild respiratory depression	Degraded by carbon dioxide absorber into compound A Possible transient mild renal impairment

The most commonly used volatile inhalational agents are isoflurane, sevoflurane, and desflurane. These halogenated anesthetics are nonflammable and sufficiently potent to be administered as a single anesthetic agent. Halothane was a common agent for many decades, especially in children who needed a mask induction; however, it has been mostly replaced by sevoflurane, which has many advantages, including a smoother mask induction, quicker emergence, less myocardial depression, less arrhythmogenic potential, and a smaller incidence of postoperative liver dysfunction. These halogenated anesthetics have similar effects on cardiac and pulmonary function. In a dose-dependent manner over usual clinical doses, these agents increase heart rate and decrease systemic vascular resistance and blood pressure while minimally decreasing cardiac output. Pulmonary effects include a dose-dependent increase in respiratory rate and $PaCO_2$ while decreasing tidal volume and minute ventilation. Increased atelectasis under anesthesia leads to an increased shunt; this usually necessitates an inspired oxygen fraction of at least 25% to 30% to maintain reasonable hemoglobin saturation. Small concentrations of these agents severely depress the ventilatory response to acute hypoxia; therefore, patients must be closely monitored after extubation while being transferred to the post anesthesia care unit (PACU).

Sevoflurane and desflurane are nonflammable, volatile, halogenated agents that are completely fluorinated analogues of isoflurane. Because of low lipid solubility, both agents produce rapid awakening from general anesthesia compared with isoflurane; this difference in emergence time is pronounced in obese patients after prolonged surgery. Because of a high vapor pressure, desflurane requires a special vaporizer to deliver clinically useful concentrations of the gas. Sevoflurane is gentle on the airway and is the preferred agent by most anesthesiologists in pediatric patients that require a mask induction. Although preferred for their quick awakening properties, sevoflurane and desflurane are more costly than isoflurane.

The use of potent inhalational agents for maintenance of anesthesia offers several advantages in head and neck patients. First, the agents decrease bronchoconstriction by relaxing bronchial smooth muscle. Second, they produce reasonable muscle relaxation without the use of neuromuscular blocking drugs, allowing assessment of facial nerve function. Third, inhalational agents produce a moderate degree of hypotension and, in concert with a 15-degree head-up tilt, can reduce surgical blood loss. Hypotension should be used cautiously in elderly patients or patients with a history of hypertension or vascular disease.

Nitrous oxide is an odorless, nonhalogenated inhaled anesthetic often added in concentrations of 50% to 70% (0.5 to 0.7 MAC). Nitrous oxide is highly insoluble, which enables a rapid emergence. It is not a potent inhalational anesthetic, and the brain concentration sufficient to render a patient unconscious may not be achieved at atmospheric pressures. In combination with a halogenated anesthetic, nitrous oxide speeds induction and emergence from general anesthesia, in addition to attenuating some of the cardiovascular and respiratory effects. Although not flammable, nitrous oxide can support combustion, especially if delivered with a high concentration of oxygen, and thus nitrous oxide should not be used during laser endoscopy. Additionally, nitrous oxide quickly diffuses into closed, air-filled body cavities to rapidly expand volume; thus, it must be avoided in the presence of obstructive ileus, pulmonary bullae, or an unrelieved pneumothorax. The middle ear also represents an anatomic air cavity vented to the atmosphere only when the eustachian tube is open. If high concentrations of nitrous oxide are used, the nitrous oxide diffuses into the middle ear faster than nitrogen is able to diffuse out, resulting in an increase in intracavitary pressure that can be great enough to rupture the tympanic membrane or dislodge a graft during otologic surgery. Therefore, common practice is to avoid nitrous oxide or to limit the concentration to 50% and to discontinue administration 30 minutes before graft placement. Nitrous oxide undergoes minimal metabolism by the liver; however, prolonged exposure to high concentrations inhibits methionine synthase activity and can cause megaloblastic or aplastic anemia, although this is not seen with routine intraoperative dosing. Nitrous oxide increases pulmonary artery pressures and should be used cautiously in patients with pulmonary hypertension.

Emergence from a general anesthetic may be more challenging in patients after upper airway procedures. Upon extubation, these patients are more likely to have laryngospasm due to irritation from secretions and blood, which may lead to rapid arterial desaturation. If the anesthesiologist is unable to give positive-pressure ventilation by mask, jaw thrust should be exerted with pressure between the mandible and the mastoid process. If laryngospasm persists, an intravenous anesthetic should be administered and then a small dose of succinylcholine (20 mg) if necessary.

All of the inhaled halogenated anesthetics are triggers for malignant hyperthermia, a rare but well-known reaction. Malignant hyperthermia occurs more commonly if succinylcholine has been used for muscle relaxation. Characteristics of malignant hyperthermia include tachycardia, markedly increasing $PaCO_2$, metabolic acidosis, sustained muscle rigidity, myoglobinuria, and an increasing temperature (may be a late sign). These are manifestations of a generalized hypermetabolic state initiated by an inhibition of calcium reuptake into the sarcoplasmic reticulum of the skeletal muscle. If not controlled swiftly, malignant hyperthermia is fatal. The principles of management include discontinuing all volatile anesthetics and succinylcholine, hyperventilating with 100% oxygen, administering dantrolene 2.5 mg/kg up to 10 mg/kg, administering bicarbonate as needed to correct the metabolic acidosis, and total-body cooling. The surgery should be stopped as soon as possible. Any patient with a history

or family history of malignant hyperthermia should not receive halogenated anesthetic agents or succinylcholine for future procedures.

Intravenous Anesthetic Agents

For most surgical procedures, the first step in production of general anesthesia is intravenous administration of a hypnotic drug, followed by maintenance of anesthesia with an inhalational agent supplemented with narcotics. The intravenous induction is usually more acceptable to the patient than inhalation induction with a volatile agent. The drugs commonly used for this purpose share the ability to produce a state of unconsciousness rapidly, which coincides with a critical peak concentration in brain tissue. Awakening occurs when this concentration decreases, usually through redistribution of the drug from brain tissue to muscle and adipose tissue. Metabolism and excretion of the drug then take place in the liver and other organs (Table 15.3), but this is only of consequence for doses larger than for induction, such as in prolonged infusions.

Barbiturates are lipid-soluble, highly alkalotic compounds, the central ring structure of which consists of a fusion of urea and malonic acid. The two subgroups, thiobarbiturates, such as pentobarbital, and oxybarbiturates, such as methohexital, are differentiated by a sulfur or oxygen molecule attached to the urea moiety. The drugs of this family generally produce unconsciousness within 3 minutes of intravenous administration, and awakening usually occurs within 10 minutes of initial dosage. Hypotension after induction with barbiturates is usually caused by direct myocardial depression and vasodilatation of the peripheral capacitance vessels, causing a decrease in the venous return, which may be dramatic in patients with uncorrected hypovolemia. Barbiturates cause respiratory depression, including apnea at normal doses for induction of anesthesia. Like any other respiratory depressant, barbiturates should be administered with caution if a possibility exists that the airway may be difficult to maintain in the absence of spontaneous ventilatory effort. Etomidate is an imidazole intravenous anesthetic agent structurally related to the antifungal drug, ketoconazole. Etomidate produces minimal derangement of cardiovascular function, so it is preferred to barbiturates in operations on patients who are hemodynamically unstable, with decreased myocardial contractility, or coronary artery disease. Etomidate has less respiratory depressant effect compared with barbiturates; however, as with any anesthetic induction agent, administration may result in airway obstruction and apnea. Rapid administration can produce impressive myoclonus, which is of no clinical significance. Etomidate is formulated in a solvent containing propylene glycol, which produces pain and phlebitis during intravenous injection. The venoirritation can be lessened with the prior intravenous injection of 20 to 40 mg of lidocaine, and myoclonus can be ameliorated with administration of sedatives or narcotics before the injection. Etomidate inhibits 11-B hydroxylase and causes adrenal suppression and thus infusions or frequent repeated doses should not be used. It is also not an ideal ambulatory drug due to its high incidence of nausea and vomiting.

Propofol is a substituted phenol with a rapid onset and short duration of action. Awakening after a dose of propofol is effortless, with little residual sedation. Propofol causes profound respiratory depression when used in induction doses. It also causes a more pronounced attenuation of upper airway reflexes, which can be useful in the manipulation of the airway without muscle relaxants (i.e., the placement of a laryngeal mask airway). Propofol causes pronounced hypotension due to peripheral vasodilatation and blocking of the normal reflex tachycardia in patients with hypovolemia or decreased left ventricular function.

TABLE 15.3 INTRAVENOUS ANESTHETIC AGENTS

Drug	Physicochemical Characteristics	Route of Metabolism	Route of Excretion	Cardiovascular Effects	Respiratory Effects	Side Effects
Barbiturates	Barbituric acid ring contains either an S or an O molecule Highly alkalotic	Liver	Kidneys	Primary myocardial depression and venodilation	Induces apnea	Histamine release Possible induction of acute porphyria
Etomidate	Imidazole	Liver (rapid)	Kidneys	Minimal	Minimal	Myoclonus Venoirritation Adrenal suppression
Propofol	Substituted phenol	Liver, possibly lung	Kidneys	Vasodilation	Minimal	Histamine release Venoirritation
Ketamine	Cyclohexanone	Liver	Kidneys	Releases endogenous catecholamines	Stimulates production of oral secretions and predisposes to laryngospasm	Hallucinations Nystagmus

Propofol, which is formulated in a soybean emulsion, causes venoirritation after intravenous administration of the drug. The brief duration of propofol activity allows patients to return quickly to preoperative levels of mental alertness, even with prolonged infusions. This short context-sensitive half-time (i.e., half-time after termination of infusion) enables propofol to be used with an analgesic as a total intravenous anesthetic. A unique feature of propofol is that it is antiemetic, making it popular for the induction and maintenance of anesthesia for brief outpatient procedures.

Ketamine is a cyclohexanone derivative similar in structure and activity to the hallucinogen phencyclidine. Ketamine is unique in its mode of action in producing a state of anesthesia in that it appears to interrupt the perception of pain at the cortical level. A patient who has received an induction dose of ketamine appears to be conscious but neither responds to, nor has memory of, painful stimuli. This effect is described as the dissociative effect of ketamine. Ketamine induces amnesia and supports blood pressure through the release of endogenous catecholamines, and unlike the other intravenous anesthetic agents, ketamine produces intense analgesia. It does not produce respiratory depression among healthy persons who have not received premedication. It also is a profound bronchodilator and seems to protect upper airway reflexes and muscle tone, although airway obstruction is possible. Additionally, ketamine enhances the production of oral secretions and increases the likelihood of laryngospasm and thus should be used cautiously in patients with asthma or chronic obstructive pulmonary disease. Emergence from ketamine anesthesia can appear smooth, but patients may have hallucinations during the recovery period. These psychotomimetic effects can be attenuated with prior administration of benzodiazepines or propofol.

ANCILLARY AGENTS

Intravenous Sedative Agents

Benzodiazepines are one of the most useful drug families in anesthesiology, as they are commonly administered as premedicants to reduce anxiety and are also helpful for patients undergoing regional anesthesia. Midazolam is the most commonly used preoperative sedative as it is painless on injection, unlike diazepam, and a quicker onset and shorter duration of action compared with lorazepam. In preinduction doses of 1 to 3 mg iv, midazolam produces reliable anxiolysis, sedation, and amnesia without prolonging emergence. Benzodiazepines should be administered with care to patients with respiratory insufficiency or obstructive sleep apnea, as these patients appear to be more sensitive to the suppression of the ventilatory drive to CO_2. If oversedation occurs, benzodiazepines may be reversed with repeated doses of flumazenil 0.2 mg iv. Benzodiazepines reduce cerebral blood flow and metabolism and are effective in the control of grand mal seizures.

Narcotic Agonists and Antagonists

Narcotic agonists are a cornerstone of current anesthesia practice. Although the currently available narcotics differ widely in chemical structure, they share the ability to bind to specific opiate-receptor sites in the brain and spinal cord. The prototype mu-opioid receptor is responsible for producing analgesia and the narcotic side effects of meiosis, respiratory depression, bradycardia, constipation, and urinary retention. The other opioid receptors include kappa, delta, and sigma. The pharmacodynamics of opioids depend on the type of receptor activated and its affinity.

Morphine, a naturally occurring opium derivative, has been used for centuries as an analgesic and antidiarrheal agent. Morphine is fairly insoluble in lipids and effective when administered by the intramuscular, intravenous, epidural, or intrathecal route. It is inexpensive and possesses a long duration of action, although its high un-ionized fraction and low lipid solubility make its onset slow (15 to 30 minutes). Morphine can be used for premedication, postoperative pain control, or as an adjuvant to an intraoperative anesthetic. Pure nitrous narcotic techniques (nitrous oxide plus morphine) are rarely used now because of the high incidence of intraoperative awareness. The respiratory depressant effects of morphine are well known. Even a small dose can produce abrupt apnea among elderly or debilitated patients. Histamine release can cause a decrease in systemic vascular resistance and profound hypotension among patients with hypovolemia. Morphine has hepatic and renal pathways of metabolism and is excreted into the bile and the urine. However, the accumulation of active metabolites of morphine (morphine 3-glucuronide and morphine 6-glucuronide) can occur in patients with renal failure, causing narcosis and respiratory depression. Many practitioners have replaced morphine with hydromorphone because it has a similar duration of action with no histamine release or active metabolites.

Use of the potent, synthetic narcotics alfentanil, sufentanil, and fentanyl is usually restricted to the operating room, where equipment for ventilatory support is readily available. These drugs contain a piperidine ring and are noteworthy for their production of rapid, intense analgesia. Fentanyl and sufentanil are approximately 100 and 1,000 times as potent as morphine, respectively. With the onset of analgesia, abrupt, profound respiratory depression can occur. Fentanyl and sufentanil are lipid soluble and have a rapid onset of action (1 to 2 minutes) and peak effect (under 5 minutes). They can maintain cardiovascular stability even in large doses. Both drugs are metabolized by hepatic microsomal systems and excreted into the urine. Alfentanil, however, is fairly insoluble in fatty tissues. Its volume of distribution is much smaller than that of fentanyl or sufentanil, and a greater quantity of the drug is immediately available for hepatic degradation. These pharmacokinetic properties cause a shorter duration of activity

than is seen with fentanyl, especially after prolonged infusions. Profound bradycardia and hypotension can occur even among healthy persons after rapid intravenous administration of alfentanil; therefore, it should be given carefully to patients in hemodynamically unstable condition. Additionally, when given in large doses, opioids can cause chest wall rigidity, impairing ventilation. This condition is mediated through central mechanisms and can be treated with muscle relaxants.

Remifentanil is an ultrashort-acting opioid within the piperidine series of narcotics. It is metabolized rapidly by nonspecific plasma esterases, and thus, rapid awakening with little drug hangover and no residual analgesia are hallmarks of this drug, regardless of the duration of infusion. It is usually administered as an infusion, with doses ranging from 0.1 to 1 mg/kg/min, and it reliably suppresses autonomic and hemodynamic responses to surgical stimulation. Because of cost constraints and the fact that rapid shutoff of analgesia is undesirable in most surgical settings, the use of remifentanil is often limited to short endoscopic procedures or neurosurgical procedures requiring immediate postoperative neurologic assessment. Another drawback is the rapid tolerance that develops in patients on remifentanil, which has been demonstrated to necessitate increased postoperative opioid requirements (5). During emergence from anesthesia, it is important to implement a plan for postoperative analgesia in a timely fashion.

Naloxone antagonizes residual respiratory depression or other unwanted side effects that occur with opioids. Careful titration of naloxone (e.g., 1 mcg/kg iv q 2 minutes) may enable reversal of respiratory depression without a significant effect on analgesia or hemodynamic parameters. Additionally, one must be aware that the effects of naloxone can dissipate before metabolism of the narcotic is complete, and precipitate respiratory depression can occur.

Butorphanol, nalbuphine, and buprenorphine are drugs with mixed opiate agonist and antagonist properties. The advantage over pure narcotic agonists is production of analgesia with less risk of respiratory depression, although there is a ceiling effect on analgesia and these drugs are less commonly used than narcotic agonists perioperatively.

Neuromuscular Blocking Agents and Antagonists

Muscle relaxants claim a critical role in modern anesthesia practice (Table 15.4). They facilitate endotracheal intubation and enhance the intrinsic muscle-relaxant properties of inhalational halogenated agents. In otolaryngologic surgery, management of muscle relaxation can be particularly difficult. Periodic assessment of the integrity of the facial nerve is essential for the success of many types of surgery involving the ear or parotid gland. Eliciting a facial grimace by means of direct electrical stimulation of the nerve is the easiest method of facial nerve identification. A common approach is to avoid nondepolarizer muscle relaxants and use a high dose of an inhalational agent to produce a moderate degree of relaxation.

TABLE 15.4 NEUROMUSCULAR BLOCKING DRUGS

Drug	Physicochemical Characteristics	Route of Metabolism	Route of Elimination	Cardiovascular Effects	Approximate Onset of Maximum Block (min)	Approximate Duration of Activity (min)
Competitive inhibitors						
Atracurium	Benzylisoquinoline	pH-dependent Hoffman degradation	Kidneys	Hypotension from histamine release in large doses, CNS toxicity	3	40–60
Cisatracurium	Benzylisoquinoline	pH-dependent Hoffman degradation	Kidneys	None	2–3	40–60
Pancuronium	Steroid nucleus	Liver	Mainly kidneys	Tachycardia	3–4	60–90
Vecuronium	Steroid nucleus	Liver	Kidneys and liver	None	2–3	40–60
Rocuronium	Steroid nucleus	None	Kidneys and liver	None	1–2	40–60
Noncompetitive inhibitors						
Succinylcholine	Linear molecule that is a fusion of succinic acid and choline	Plasma cholinesterase	Kidneys	Bradycardia among children or when repeat bolus to adults	0.5–1 if no competitive inhibitor is given to block fasciculations	<10 but may be prolonged in presence of cholinesterase deficiency

The two major categories of relaxant drugs are competitive and noncompetitive inhibitors of neuromuscular transmission. The common site of activity for these drugs is the postsynaptic membrane of the nicotinic cholinergic receptor. Competitive blocking agents (nondepolarizing drugs) bind loosely to the receptor site and compete with acetylcholine in a concentration-dependent manner. Noncompetitive blocking agents (depolarizing drugs) bind strongly to the receptor site and mimic the electrophysiologic effect of acetylcholine at the end plate, depolarizing the membrane and rendering it incapable of further stimulation.

Succinylcholine is the only clinically used depolarizing neuromuscular blocking drug. It is similar in structure to acetylcholine and imitates its effects at the motor end plate. Muscle fasciculation heralds the onset of succinylcholine-induced paralysis unless specific measures are taken to block this effect. The drug has a rapid onset of action (less than 60 seconds) and a short duration of activity (less than 10 minutes) owing to its rapid metabolism by plasma cholinesterases, such that only a small fraction of the dose given actually reaches the neuromuscular junction. This pharmacokinetic profile makes the drug useful in the induction of anesthesia and in intubation for procedures in which muscle paralysis is not desired. Rarely, succinylcholine can be administered by means of intermittent bolus or continuous infusion; however, prolonged paralysis can occur if excessive doses are administered by either route. Succinylcholine can produce profound bradycardia mediated by stimulation of cardiac muscarinic receptors, especially in young children or if a repeat dose is given within several minutes. However, pretreatment with a small dose of atropine or glycopyrrolate blocks this phenomenon. Patients with abnormal or decreased cholinesterase will have a prolonged response to the action of succinylcholine. Potassium efflux from the intracellular fluid due to the activation of receptors is the unavoidable consequence of succinylcholine action. The average elevation of potassium concentration in the serum after a dose of succinylcholine is 0.5 to 1.0 mEq/L. For a healthy person with a normal preoperative potassium level, this elevation is of no physiologic significance; however, life-threatening hyperkalemia can develop among patients with massive crush injuries, burns, or paraparesis due to extrajunctional receptor release of potassium. Succinylcholine must also be avoided in patients with elevated baseline potassium levels, as in some patients with renal failure. Therefore, in these situations, succinylcholine must not be given. This drug also is a triggering agent for malignant hyperthermia, similar to the volatile anesthetics. In children, rhabdomyolysis, hyperkalemia, and cardiac arrest have been described, especially in those with previously undiagnosed myopathies. Because of these risks, succinylcholine should not be used in pediatric patients unless there is a clear indication, such as to prevent aspiration in a patient with gastric contents. Other side effects of the drug include increases in the intraocular and intracranial pressure soon after injection.

The nondepolarizing drug tubocurarine (curare) is the prototype of the benzylisoquinoline competitive neuromuscular blocking agents; however, it has been replaced by other drugs in its class, including atracurium and cisatracurium. Rapid boluses of atracurium result in histamine release and a consequent drop in blood pressure and increase in heart rate. Cisatracurium is a stereoisomer of atracurium and does not cause histamine release or hemodynamic changes. These drugs are not dependent on liver or kidney function for elimination and thus are popular for patients with liver or renal failure. Pancuronium, vecuronium, and rocuronium are competitive, nondepolarizing muscle relaxants that contain a steroid nucleus. Pancuronium has a 90-minute duration of activity, which is the longest of the clinically used muscle relaxants. It is degraded in the liver into potent active metabolites and is excreted primarily by the kidneys. Unlike vecuronium and rocuronium, which are hemodynamically stable, pancuronium produces a marked increase in heart rate after intravenous administration, in part because of its strong anticholinergic activity at the cardiac muscarinic receptors and in part because of its ability to block norepinephrine reuptake into presynaptic nerve terminals. These properties can cause atrial and ventricular tachydysrhythmia if the drug is given in combination with halothane, cocaine, or epinephrine-containing local anesthetic solutions. Most nondepolarizers have onset times ranging from 2 to 5 minutes, depending on the dose of administration and use of a priming dose. The only exception to this is high dose rocuronium (1.2 mg/kg), which can produce ideal intubating conditions in 60 seconds and is preferred in rapid-sequence inductions when succinylcholine is contraindicated. Examples of anticholinesterase agents used to terminate the effects of muscle relaxants include edrophonium and neostigmine. Each agent contains a quaternary ammonium group that renders the drug poorly soluble in body lipids. Edrophonium binds loosely and reversibly to acetylcholinesterase through a combination of electrostatic and hydrogen bonding to produce a rapid onset of action and a short duration of activity. Neostigmine, however, binds more tightly to acetylcholinesterase. The result is a longer onset of action and a longer duration of activity. Anticholinesterase agents block the activity of plasma cholinesterase and prolong the paralysis produced by succinylcholine. Administration of an inhibitor of acetylcholinesterase increases the amount of acetylcholine available for binding to the postsynaptic nicotinic receptors of the neuromuscular junction and to the muscarinic receptors in the parasympathetic ganglia. Stimulation of these muscarinic receptors produces bradycardia, salivation, bronchoconstriction, and an increase in gastrointestinal motility. These unwanted side effects can be blocked by the properly timed administration of an anticholinergic drug, such as atropine or glycopyrrolate. Drug pairs are selected with an effort to match respective time of onset and duration of activity, so atropine frequently accompanies edrophonium,

and glycopyrrolate commonly accompanies neostigmine. In Europe, sugammadex has been used as a specific antagonist to steroid-containing muscle relaxants, such as rocuronium. Sugammadex administration reverses neuromuscular blockade within 2 minutes without any hemodynamic effects (6). Safety concerns regarding sugammadex have delayed its approval in the United States.

Incomplete reversal of neuromuscular blockade is a frequent occurrence and accounts for critical respiratory events in the PACU, such as severe hypoxemia and upper airway obstruction (7). Reversal of paralysis is especially important in patients after undergoing upper airway surgery where edema and blood in the airway necessitate a strong cough and respiratory effort. Reversal of neuromuscular blockade may be assessed by a nerve stimulator and tests of strength, including a strong hand grip or 5-second head lift.

Antiemetics

Patients are at increased risk of postoperative nausea and vomiting (PONV) after undergoing ENT surgery, especially surgery on the inner ear. Vomiting after upper airway surgery may lead to complications and a high rate of patient dissatisfaction. The anesthesiologist has several classes of drugs to reduce the incidence of PONV, including steroids (dexamethasone 4 mg iv at the start of case), 5-HT3 antagonists, (ondansetron 4 mg iv at end of case), butyrophenones (haldol 0.5 to 2 mg iv), and promethazine (6.25 to 12.5 mg iv) (8). These drugs are most effective when used in combinations, and multiple intraoperative antiemetics should be given in patients with multiple risk factors for PONV (e.g., nonsmoker, female, h/o PONV, and postoperative opioids). These drugs are inexpensive and have only rare side effects, although promethazine causes sedation.

ANESTHESIA MONITORING

Technical improvements in anesthesia machines and respiratory and hemodynamic monitoring enable successful administration of anesthesia to patients who previously were considered too ill for surgery. Alarm systems that announce anesthesia circuit disconnection or warn of a hypoxic inspired gas mixture are standard features on modern anesthesia machines. Tissue oxygenation is assessed continuously with the noninvasive technique of pulse oximetry, and ventilation is monitored with real-time capnography. Despite modern technology, emergencies do occur, for which the anesthesiologist and surgeon must be aware (Table 15.5).

The Anesthesia Machine

The anesthesia machine consists of oxygen and anesthetic vapor delivery systems, a reservoir bag or ventilator used to assist patient ventilation, and a circuit that provides a conduit through which anesthetic gases or oxygen reach the patient. Oxygen flows to the patient from a wall source or an oxygen tank attached to the anesthesia machine. The rate of administration is controlled with calibrated flowmeters. Nitrous oxide, air, and helium also can be given in a similar manner. Inhalational anesthetic agents can be added to the inspired mixture by allowing the carrier gas to flow over and evaporate a pool of liquid anesthetic contained in an agent-specific vaporizer. The vaporizer accurately controls

TABLE 15.5 EMERGENCIES ANESTHESIA

Emergencies	Signs	Treatment
Malignant hyperthermia	Increased $ETCO_2$, rigidity, tachycardia, respiratory and metabolic acidosis, increased temperature (often a late sign), myoglobinuria	Discontinue the triggering agent, hyperventilate with 100% oxygen, stop procedure if possible, dantrolene 2.5 mg/kg, bicarbonate as needed, cool patient
Local anesthetic toxicity	Agitation, seizures, unconsciousness, ventricular dysrhythmias, cardiac arrest	100% O_2, midazolam if CNS effects, ACLS protocol for cardiac arrest, consider 20% lipid emulsion
Anaphylaxis	Hypotension, tachycardia, bronchospasm, hypoxia, urticaria, edema	Discontinue drug, 100% O_2, epinephrine, steroids, antihistaminics
Laryngospasm	Spasm of the laryngeal musculature due to secretions	Positive-pressure ventilation through a bag/mask with 100% O_2, succinylcholine if necessary
Latex allergy	Same as allergy/anaphylaxis	Treat same as anaphylaxis
Bronchospasm	Hypoxia, wheezing, increased airway pressures	Deepen anesthetic, β-adrenergic agonist, epinephrine

the amount of anesthetic vapor allowed to saturate the carrier gas and directly regulates the concentration of inhaled anesthetic. The anesthesiologist adjusts the depth of anesthesia by increasing or decreasing the amount of anesthetic vapor introduced into the delivery system. The anesthetist often monitors the end-tidal concentrations of inhalational agents that correlate to the patient's brain concentration. A reservoir bag or automatic ventilator is used to assist or control the patient's breathing. Newer anesthesia machines (e.g., the GE Aespire View) have multiple options for controlling ventilation, which rival ICU ventilators, including the ability to deliver up to 30 cm H_2O of PEEP, a peak inspiratory pressure of 60 cm H_2O, and a pressure-controlled volume-guaranteed mode. These machines with advanced ventilators are helpful in managing trauma patients or patients with severe lung disease.

An anesthesia breathing circuit makes the final connection between the machine and the patient. The inspiratory limb of a breathing circuit conducts each anesthetic-laden, oxygen-enriched breath from the machine to the patient. The expiratory limb of the circuit routes expired gas containing carbon dioxide through an adjustable relief valve into a scavenging system. One-way valves and an internal carbon dioxide absorber prevent rebreathing by the patient of any carbon dioxide–laden gas not vented into the scavenging system. An oxygen monitor with electronic alarm is located in the inspiratory limb of the breathing circuit to detect any deviation of the oxygen concentration from preset limits. This monitor is a necessary component, in a series of interconnected safety mechanisms, designed to prevent the catastrophic administration of a hypoxic gas mixture to the patient. Other links in this safety chain include an alarm and a cutoff valve that terminates nitrous oxide flow when oxygen line pressure is low.

Intraoperative Monitoring

Continuous, noninvasive measurement of arterial hemoglobin saturation is possible with pulse oximetry. A light-emitting diode is placed on a finger, toe, earlobe, or other appropriate area on the body, and shines two different wavelengths of light (660 and 940 nm) through the tissue. Oxyhemoglobin and reduced hemoglobin absorb light differently; thus, using the Beer law, the ratio of the absorbance spectra of these two wavelengths is calculated and expressed as percentage oxygen saturation. The oximetry unit does not directly measure Pao_2, and the pulse oximeter continuously displays a saturation of at least 98% through a range of Pao_2 values between 150 and 550 mm Hg. As the unit does not indicate a decrease in arterial saturation until Pao_2 decreases to less than approximately 100 mm Hg, a pulse oximeter is not useful for detecting a downward trend in arterial oxygen tension until Pao_2 decreases below this level. Depending on the shape of the oxygen–hemoglobin dissociation curve, an oxygen saturation of 90% usually correlates with a Pao_2 of 60 mm Hg.

Although pulse oximetry reliably detects arterial desaturation for most patients, limitations exist. A malpositioned sensor or nail polish may result in an inaccurate reading. Ambient light or the injection of biologic dyes such as methylene blue can artificially decrease the hemoglobin saturation displayed. Carboxyhemoglobin in patients who smoke tobacco or with carbon monoxide poisoning will read at the same level as oxyhemoglobin, causing an erroneous increase in saturation. Additionally, electrocautery or patient movement can cause mechanical interference with signal processing, and vasoconstriction initiated by hypovolemia, hypothermia, or hypotension can be so intense that the oximeter cannot detect pulsatile flow or determine a saturation value.

The adequacy of ventilation can be monitored continuously with capnography, a method of detecting the amount of carbon dioxide in expired gas. The actual measurement can be obtained with two different tools—an infrared analyzer or a mass spectrometer. Both methods provide nearly instantaneous feedback of the concentrations of oxygen, carbon dioxide, and inhalational agents in the inspired and expired gas. Infrared analysis is most commonly used and is based on the absorption of infrared light by carbon dioxide at specific optimal wavelengths (between 4,200 and 4,300 nm). Mass spectroscopy works on the principle of separating charged gases based on their molecular weights. Although mass spectroscopy is the gold standard monitor, these units are more expensive than infrared devices.

In anesthesia, capnography is necessary for monitoring and adjusting patient ventilation, but it also is helpful in other clinical situations. First, the absence of carbon dioxide in the expired gas of a patient after attempted intubation can indicate that the endotracheal tube is in the esophagus. Second, a rapid decrease in the baseline value of expired carbon dioxide can be caused by a decrease in the amount of blood entering the pulmonary circulation causing an increase in dead space, a circumstance that can occur after severe intraoperative hypovolemia, pulmonary thromboembolism, or an air embolism. An air embolism may occur during operations near the large veins in the neck, which are above the level of the heart in a sitting patient, thus encouraging air to be entrained back to the right atrium. If an air embolism is suspected by the anesthetist, the surgeon should be immediately notified so that attempts to prevent further air entrapment are initiated. Third, a failure of the carbon dioxide waveform to return to zero during inspiration indicates rebreathing due to either a faulty valve or an exhausted absorbent.

Hemodynamic Monitoring

The anesthesiologist may need to monitor intravascular volume status if there is anticipated large volume blood loss, for example, during extensive head and neck cancer surgery. Basic volume status assessments include blood pressure, heart rate, urine output, and calculations of

preexisting fluid deficit and ongoing maintenance and surgical losses. Other tools such as central venous pressure (CVP), systolic pressure variation, or esophageal Doppler monitoring enable a more accurate assessment. The internal jugular veins should be avoided for CVP monitoring during neck surgery; however, the subclavian vein carries a higher risk of pneumothorax. An arterial line has minimal risk and can be used to calculate the systolic pressure variation or pulse pressure variation with positive-pressure breathing, both of which are excellent predictors of hypovolemia that will respond to fluid administration (9). Guiding intraoperative fluid administration with an esophageal Doppler to continuously monitor preload and cardiac output has proven to reduce hospital time and decrease complications (10).

Temperature Control

Airway procedures may make it necessary to measure a patient's temperature in areas other than the esophagus, such as bladder (urinary catheter probe) or axilla. Forced air warming has been successful in maintaining patients' temperatures greater than 36 degrees centigrade, which reduces perioperative morbidity and mortality.

Depth of Anesthesia

There are several available depth of anesthesia monitors, the most common of which uses bispectral technology. A probe is placed on the patient's forehead to record the electroencephalogram, which is displayed as a number between 0 (isoelectric) and 100 (awake). The likelihood of intraoperative awareness (~0.2% in all cases) is reduced if the bispectral index (BIS) is kept below 60, and recovery time is reduced if the BIS is kept above 40 (11). However, the BIS has not proven better in preventing intraoperative awareness than monitoring the expired gas concentration.

AIRWAY MANAGEMENT

Assessing the Airway

Careful preoperative airway assessment is essential for the safe induction of anesthesia. Difficulty in managing the airway is the single most important cause of anesthesia-related morbidity and mortality. Successful management of a difficult airway begins with recognition. Acute airway compromise needs immediate attention and may be exhibited by tachypnea, accessory muscle use, stridor, or hypoxia. In stable patients, one should acquire a thorough history with special reference to symptoms that suggest airway abnormalities, such as hoarseness, dyspnea, orthopnea, dysphagia, or a history of previous head or neck disease. Additionally, a history of previous airway difficulties with intubation should be explored, and any available anesthesia records from previous intubations must be reviewed. The ease of direct laryngoscopy and intubation must be evaluated in all patients. During the preoperative physical examination, the following characteristics may indicate the presence of a difficult airway: long upper incisors, overbite, interincisor distance less than 3 cm, highly arched or narrow palate, a bull neck, and decreased neck extension (12). The inability of the patient to protrude mandibular incisors anterior to the maxillary incisors is also predictive of a difficult intubation. In addition, a distance of less than three fingerbreadths between the mentum and the thyroid cartilage (the thyromental distance) is a nonreassuring finding and may be affected by previous surgery or radiation. To assess temporomandibular joint mobility and the adequacy of the oral cavity, the patient should be asked to open his or her mouth as widely as possible and fully extend the tongue. At this time, the mouth should be examined for loose teeth, prostheses, or an unsuspected mass. The size of the tongue relative to the actual size of the oral cavity can be visually graded by using the Mallampati scoring system. This test is performed with the patient in a seated position with his or her head in a neutral position and mouth opened as wide and tongue protruded as far as possible. Classification is then determined, depending on the visible structures. When the tip of the uvula, tonsillar pillars, and soft palate are visible, the grading is class I and usually corresponds to a complete visualization of the cords or a grade 1 view. When the tonsillar pillars and the base of the uvula are visible, with the tip of the uvula obscured by the posterior tongue, the grading is class II. Progressive difficulty in intubation usually corresponds to a limited view of the pharyngeal structures, including a view of only the soft palate (class III) and the hard palate (class IV). Predictive values of single tests have not been found to be high; however, by using several different tests, most patients with potentially difficult airways can be identified and managed appropriately.

The airway of some patients may be difficult to manage during induction because of an underlying pathologic condition, such as head and neck cancer, obstructive sleep apnea, facial trauma, or congenital abnormalities. Predictors of difficult mask ventilation include a body mass index greater than 30, history of snoring, age greater than 57, severely limited jaw protrusion, and the presence of a beard (13). Long-standing rheumatoid arthritis can cause atlanto-occipital subluxation and extreme laryngeal deviation. Patients who have intrathoracic tracheal compression from extensive mediastinal adenopathy, retrosternal goiter, or massive neoplasia in the anterior mediastinum can prove easy to intubate but impossible to ventilate if the mass obstructs the trachea after loss of spontaneous respiration. In many cases, the surgeon has evaluated the pathologic condition that makes the airway abnormal and a preprocedure discussion between the anesthetist and otolaryngologist is imperative. Patients scheduled for laryngectomy may have undergone radiation therapy to the head and neck that caused epiglottis fibrosis, laryngeal edema, or trismus.

Partial airway obstruction from laryngeal or oropharyngeal masses may already exist and necessitates careful planning of intubation techniques. One study demonstrated a four-fold increased risk of failed Glidescope (video laryngoscope, Verathon Inc., Bothell, WA) intubation in patients with a neck scar, radiation, or mass (14). Ventilation or intubation of patients with some congenital anomalies can be impossible if apnea occurs. These syndromes include Beckwith-Wiedemann, Crouzon, Down, Goldenhar, Pierre Robin, Treacher Collins, and Turner syndromes; congenital rubella; and mucopolysaccharidosis.

Thorough study of an airway found to be abnormal before surgery can prevent catastrophe during induction of anesthesia. In addition to history and physical exam, the size, site, and degree of obstruction of an airway lesion may be elucidated through direct visualization or radiologic scans. Flow-volume loops are helpful in assessing the degree of tracheal obstruction caused by large cervical or intrathoracic masses. Presence of a tracheal mass may necessitate maintaining spontaneous breathing until the endotracheal tube is placed distal to the mass to prevent tracheal obstruction that may result from positive-pressure mask ventilation. Fiberoptic laryngoscopy or tracheobronchoscopy performed with topical anesthesia with the patient awake and breathing spontaneously can be invaluable in the evaluation of a patient who has grossly distorted anatomic landmarks.

Securing the Airway

After completion of the airway assessment, a plan can be constructed for securing the airway. There are multiple management decisions, including awake versus asleep intubation, noninvasive versus invasive techniques (e.g., tracheostomy or cricothyrotomy), and whether or not to preserve spontaneous ventilation. If no suspicion of a difficult airway exists, routine intubation can be performed, although the anesthesiologist must always have backup plans for an unanticipated difficult airway. If the airway seems as if it may be difficult to manage, securing the airway with the patient awake and spontaneously breathing may be the safest route. Anesthetizing the airway is accomplished with nerve blocks (e.g., bilateral glossopharyngeal and superior laryngeal nerves) and transtracheal injection of 4% lidocaine or with inhaled nebulized and sprayed local anesthetics (e.g., 6 mL total of 4% lidocaine). Administering glycopyrrolate (0.2 to 0.4 mg iv) 30 to 60 minutes prior to arrival in the operating room will reduce secretions and thus improve the topicalizaton and the laryngoscopic view. The patient may then be judiciously sedated with a patient appropriate combination of midazolam (anxiolysis and amnesia), fentanyl (attenuates cough reflex), and dexmedetomidine (up to 1 mcg/kg iv over 15 minutes) while the airway is anesthetized. The airway is then usually secured with fiberoptic intubation, although other awake options include direct laryngoscopy (including video-assisted techniques such as the Glidescope or CMAC [Karl Storz, El Segundo CA]), or retrograde intubation. In the case of severe anatomical abnormalities or a glottic lesion, a transtracheal catheter with subsequent jet ventilation or tracheotomy with local anesthesia may be the initial plan. In pediatric or uncooperative patients, an awake intubation may not be an option, and a gentle mask induction while keeping the patient spontaneously breathing, followed by a fiberoptic intubation may be the best alternative. However, as the patient deepens with anesthesia, airway collapse with subsequent difficulty in ventilation is possible.

If the decision is to perform an asleep intubation, preoxygenation with 100% oxygen prior to induction allows the anesthetist several minutes to intubate in case of difficulty with mask ventilation or intubation (15). If the trachea is unable to be intubated with direct laryngoscopy, successful positive-pressure ventilation with mask and reservoir bag allows for consideration of many airway techniques in the armamentarium of a well-trained anesthesiologist. Most anesthesiologists are skilled in several, but not all, techniques of management for a difficult airway and should use the techniques that work best for them. The anesthetist also must be prepared to use several techniques should one or more fail. Fiberoptic intubation is the most widely used of the second-line intubation techniques, although disrupted or severely abnormal anatomic features or bleeding in the airway can preclude successful navigation of the airway by all but the most expert endoscopists. Video-assisted laryngoscopes, light wand, gum elastic bougie, and retrograde intubation are all options, depending on the skill set of the anesthesia team. A combination of video-assisted laryngoscope with a fiberoptic scope has also proven successful. Care should be taken to avoid multiple intubation attempts, as this may lead to airway edema and difficulty with mask ventilation. Oral and nasopharyngeal airways are useful in the ventilation of patients with obstruction at the level of the oral cavity and oropharynx, respectively. If intubation fails and mask ventilation is difficult despite two provider ventilation (one provider gives two-handed jaw thrust and the other provider compresses the bag), then an laryngeal mask airway (LMA) should be inserted. Failure of the LMA necessitates emergency airway ventilation, such as a rigid bronchoscope by the otolaryngologist or transtracheal jet ventilation. If this is unsuccessful, emergent invasive airway access must be obtained by either cricothyrotomy or tracheotomy. Chapters 63 and 64 contain a further discussion of airway management, tracheotomy, and cricothyroidotomy.

Extubation of a patient who was a difficult intubation also requires careful planning. It may be beneficial to remove the endotracheal tube over an intubating stylet, which may remain in the trachea to facilitate reintubation until adequate spontaneous ventilation is assured.

There may be some cases for a general anesthetic where the anesthesiologist decides that the airway does not need to be secured with an endotracheal tube and a laryngeal

mask airway is preferred. Compared with endotracheal intubation, an LMA is placed without muscle relaxant, it is inserted blindly, and there are fewer hemodynamic changes with placement and less coughing with emergence. Although an endotracheal tube is considered a more secure airway for most ENT surgery, an LMA offers improved emergence and better airway protection during nasal surgery (16).

ANESTHETIC CONSIDERATIONS FOR ENDOSCOPIC PROCEDURES

For a conscious, cooperative patient, careful orotracheal topical anesthesia and intravenous sedation may be adequate for the performance of brief, atraumatic laryngoscopic procedures, such as vocal cord injection. For more complicated procedures, general anesthesia is induced and an endotracheal tube may or may not be inserted. In most procedures, a small-diameter, cuffed endotracheal tube (e.g., microlaryngeal tube with internal diameters of 5 mm and a high volume, low pressure cuff) does not obstruct the view of the larynx and allows efficient gas exchange and protection of the airway from blood; however, some surgical techniques necessitate complete absence of an endotracheal tube. In these situations, intravenous agents and neuromuscular relaxants meet the requirements of general anesthesia, whereas oxygenation and ventilation occur through a ventilating laryngoscope or an Albert Sanders injector. High-frequency positive-pressure ventilation is an alternative approach. Topical anesthesia combined with general inhalational or intravenous anesthetics also can be used for bronchoscopy. A ventilating bronchoscope provides an avenue for gas exchange, although apneic oxygenation with insufflation of oxygenation through a small-bore catheter placed above the carina is sometimes necessary. High rates of fresh gas flow from the anesthesia machine are needed to compensate for the leak that occurs around the bronchoscope. As in laryngoscopy, pulse oximetry is essential for monitoring patient safety, and a small dose of glycopyrrolate facilitates visualization by reducing secretions.

A controversy exists over the best type of endotracheal tube to minimize the risk of airway fire during carbon dioxide laser laryngoscopy or bronchoscopy. All tubes, except metal or ceramic, can ignite in the airway under appropriate conditions. Many anesthesiologists use laser-resistant endotracheal tubes or an ordinary polyvinyl chloride or red rubber endotracheal tube that has been closely wrapped its entire length with metallic tape designed to reflect the energy of the laser away from the tube. The cuff should be filled with normal saline tinted with methylene blue to make it apparent if the cuff is punctured. Because the cuff remains uncovered, an explosion or fire can occur if the laser beam penetrates it. A less serious problem is misdirection of the laser should the beam come into contact with the reflective tape. Even a properly wrapped laser tube can ignite if the endoscopist directs a high-wattage beam of collimated light at a single spot on the tube for too long. Management of a laser fire in the airway demands immediate disconnection of the circuit from the endotracheal tube, removal of the burning tube, extinction of the flame with normal saline, reestablishment of ventilation, and then bronchoscopy to remove debris and assess residual damage to surrounding tissues (17).

Other measures used to reduce the risk of airway fire include the avoidance of nitrous oxide, use of less than 30% inspired oxygen, a helium–oxygen rather than an oxygen–air inspired gas mixture, and packing the trachea around the cuff of the endotracheal tube with wet sponges. Additionally, all operating room personnel should wear protective goggles, and the eyes of the patient should be covered to prevent corneal or retinal thermal injury.

PREOPERATIVE PREPARATION

Evidence-based fasting guidelines by the American Society of Anesthesiologists have been established to reduce the incidence of perioperative aspiration, which carries a high risk of morbidity (18). Liquids (e.g., soda, apple juice, water, black coffee or tea) are rapidly cleared from the stomach (half-life 11 minutes), and thus, they may be ingested in unlimited quantities up to 2 hours prior to surgery. Breast milk may be given within 4 hours. A light meal, such as toast and milk should not be taken within 6 hours of surgery. Full meals with fat or alcohol delay stomach emptying and an 8-hour fast is usually recommended. If the patient has delayed stomach emptying (e.g., diabetic gastroparesis), a decision may be made to prolong the fasting guidelines further.

Most medications should be continued on the day of surgery, with a few exceptions. In patients without heart failure, angiotensin converting enzyme inhibitors and angiotensin receptor blockers should be withheld because they may cause profound and resistant hypotension when combined with general anesthetics. Insulin needs to be adjusted as is outlined in Chapter 3. A patient's cardiologist should be consulted regarding perioperative anticoagulation in patients with coronary artery stents. Patients with stents should always continue their aspirin unless there is a major concern regarding the effects from significant blood loss. Current recommendations are for patients with drug-eluting stents to have clopidogrel continued for at least 1 year and 4 to 6 weeks after bare metal stents. The concern is that the patient will be at high risk of stent reocclusion because stopping aspirin and clopidogrel each make the patient hypercoagulable, along with the hypercoagulable state of surgery.

HIGHLIGHTS

- Common local anesthetics belong to two structural classes, the amines and the esters, which differ in route of excretion.
- Local anesthetics block sodium channels intracellularly and are more effective in the base (nonionized) form because of the ease with which they enter the cell.
- With knowledge of head and neck anatomy, small amounts of local anesthesia can be used to create regional blocks of the major sensory nerves of the head and neck and permit extensive procedures under local anesthesia.
- Careful preoperative airway assessment, an understanding of basic anesthesia monitoring and airway equipment, and judicious use of anesthetic agents known to produce respiratory depression aid in the prevention of catastrophic airway loss.
- Knowledge of local anesthetics and drugs used in general anesthesia will aid in the recognition of common side effects and complications to ensure rapid treatment.
- Isoflurane, sevoflurane, and desflurane have replaced halothane as the most commonly used general anesthetics.
- Nitrous oxide is not potent enough to be used for general anesthesia by itself, but is often added to improve hemodynamic stability and speed emergence.
- Benzodiazepines produce reliable anxiolysis, sedation, and amnesia and are commonly used prior to anesthetic induction and during procedures under local anesthesia.
- Knowledge of different opioid drugs will help in the management of postoperative pain, especially in patients with advanced cancer.
- Muscle-relaxant drugs are either competitive (nondepolarizing) or noncompetitive (depolarizing) inhibitors of neuromuscular transmission that work at the postsynaptic membrane of the nicotinic cholinergic receptor.
- Knowledge of anesthetic techniques and pharmacologic principles allows safe and effective anesthetic management of nearly all otolaryngologic patients.
- Recognition of potentially difficult airways preoperatively allows not only an effective plan but also possible alternatives when necessary.
- Close cooperation between anesthesiologists and surgeons, based on a mutual understanding of needs, is essential for a successful patient outcome.

16 Endocrinology

Paul G. van der Sloot *Runhua Hou*

The endocrine system is a complex, highly integrated system of controls that plays a very important role in homeostasis. Hormone effects can be local, regional, or systemic, reflecting autocrine, paracrine, and endocrine functions. Beyond the high degree of integration within the system itself, there are complex interactions between the endocrine system and other important body systems, in particular, the nervous system. As a result, disruption of normal endocrine function often leads to systemic pathology. At the same time, manipulation of the endocrine system with drugs that block hormone receptors or drugs that mimic hormone actions can provide therapeutic benefits in a wide range of diseases.

PITUITARY

Anatomy and Embryology

The pituitary gland is one of the control centers of the endocrine system. It is composed of an anterior and posterior lobe. In some animals, but not humans, there is a distinct intermediate lobe. The anterior lobe develops by week 4 to 5 gestational age. It begins as an evagination of the ectoderm of the oropharynx known as Rathke's pouch. Eventually, the pouch is pinched off and is separated from the pharynx by the sphenoid bone. It is often referred to as the adenohypophysis. The residue of Rathke's pouch demarcates the separation between the anterior and posterior lobes. The most superior part of the pouch surrounds the neural stalk and is called the pars tuberalis. Occasionally, cells of Rathke's pouch are left behind and may form a craniopharyngioma.

The posterior lobe begins as an evagination of the floor of the third ventricle. The lumen walls eventually fuse to form the neural stalk. A small invagination in the floor of the third ventricle is also formed and is known as the median eminence. The median eminence, neural stalk, and posterior lobe form what is referred to as the neurohypophysis. Approximately 100,000 neurons of the hypothalamus project down through the neural stalk forming the hypophyseal tract. Their nerve terminals form the posterior lobe of the pituitary. In response to appropriate stimuli, these cells secrete antidiuretic hormone (ADH), also known as vasopressin, or oxytocin.

The anterior lobe cells are 50% somatotrophs secreting growth hormone (GH), 10% to 25% lactotrophs secreting prolactin, 15% to 20% corticotrophs secreting adrenocorticotropic hormone (ACTH), 10% to 15% gonadotrophs secreting luteinizing hormone (LH) or follicle-stimulating hormone (FSH), and 3% to 5% thyrotrophs secreting thyroid-stimulating hormone (TSH).

Blood supply to the pituitary is via the inferior and superior hypophyseal arteries. The capillaries of the inferior artery supplying the posterior lobe form a plexus that drains into the dural sinus. A small portion of them form the short hypophyseal portal veins that drain into the anterior lobe of the pituitary. The anterior lobe is supplied by the superior hypophyseal artery via the long hypophyseal portal veins formed by its capillaries. These veins surround the cells of the median eminence from whence neurohormones are secreted. A second plexus of fenestrated capillaries forms around the anterior lobe of the pituitary to enhance delivery of hormones to this part of the pituitary. Veins draining the anterior lobe drain into the cavernous sinus and eventually to the jugular veins.

The developed pituitary sits in a bony pouch called the sella turcica. The anterior wall is called the tuberculum sella, the posterior wall the dorsum sella. They are flanked by the anterior and posterior clinoid processes, respectively. These clinoid processes are connected by a reflection of the dura mater called the diaphragma sella. Thus, the entire sella is surrounded by dura. It is outside the arachnoid and cerebrospinal fluid and so is outside the blood–brain barrier. An important anatomical relationship is the optic chiasm, which is approximately 5 mm above the diaphragma sella and anterior to the stalk of the pituitary. Laterally, it is flanked by the cavernous sinus.

ANTERIOR PITUITARY

Growth Hormone

GH is a 19–amino acid polypeptide with two disulfide bridges and a four helical structure. It has several forms but in general has a half-life of about 20 minutes. It is considered an anabolic hormone. Its effects are mediated via insulin-like growth factors 1 and 2 (IGF1 and 2) produced by the liver and other target tissues. Cartilage growth at epiphyseal growth plates is stimulated resulting in an increase in bone mass. IGF 1 and 2 also have lipolytic effects resulting in increased lean body mass. An increase in organ size and function is also seen. GH also antagonizes insulin action resulting in insulin resistance. Its synthesis and secretion are stimulated by the release of growth hormone–releasing hormone (GHRH) from the arcuate nucleus of the hypothalamus into the hypophyseal portal system. Its secretion but not its synthesis is inhibited by somatostatin released by the periventricular nuclei of the hypothalamus. It is also inhibited via an IGF feedback loop at the level of the hypothalamus and pituitary. Ghrelin produced in the hypothalamus and by neuroendocrine cells of the gastric mucosa binds to the growth hormone secretagogue receptor stimulating GH release (1).

GH is secreted in pulsatile fashion with typically five pulses over 24 hours. The largest pulse occurs at the onset of sleep (2). Peak levels of GH occur during puberty with a general decline with age from that point. GH resistance in childhood results in Laron dwarfism, manifested by central facial dysmorphism and obesity. GH excess results in gigantism if present during development and in acromegaly if occurring in adulthood. Greater than 99% of these cases result from pituitary adenomas, usually macroadenomas. Gigantism results from hormone excess prior to epiphyseal plate closure. Acromegaly, which occurs in about 50/million population, results in increased IGF1 and subsequent proliferation of bone, cartilage, and soft tissue. Presenting symptoms include carpal tunnel syndrome, hyperinsulinemia and glucose intolerance, and hypogonadism due to decreased gonadotropin secretion. Excess GH levels may be seen in McCune-Albright syndrome (polyostotic fibrous dysplasia, precocious puberty, hyperthyroidism, hypercortisolism, and hyperprolactinemia) even though an adenoma is not present. It can also be associated with pituitary adenomas in multiple endocrine neoplasia type 1 (MEN-1). GH deficiency can be treated with hormone replacement therapy. GH excess associated with pituitary adenoma is typically treated with surgery plus or minus radiation therapy. Medical therapy can include somatostatin analogues.

Prolactin

Prolactin is a single-chain protein made of 199 amino acids with 3 disulfide bridges. It is very similar in structure to GH. Its main actions are the stimulation of breast development and milk production. It has many lesser understood functions and inhibits GHRH release. Its release is stimulated by thyrotropin-releasing hormone produced by the hypothalamus. Galanin, produced by the hypothalamus and pituitary, can also stimulate prolactin release. Inhibition occurs mainly through dopamine release by the tuberoinfundibular cells of the hypothalamus into the hypophyseal portal system. There is a negative feedback loop with prolactin stimulating tyrosine kinase activity in the tuberoinfundibular cells and subsequent release of dopamine.

Secretion of prolactin follows diurnal patterns with sleep-related increases in prolactin levels. Lactotroph hyperplasia is seen during pregnancy and lactation but usually normalizes within months of delivery. Excess prolactin occurs most commonly with dopamine antagonist drugs and primary hypothyroidism but can also be the result of other pituitary adenomas compressing the pituitary stalk. Up to 30% to 40% of pituitary adenomas are prolactinomas. Symptoms include infertility, menstrual irregularities or amenorrhea, and galactorrhea in females. Males experience a decrease in testosterone levels, decreased sperm production, and gynecomastia. Treatment of prolactin excess caused by pituitary adenomas is medical using dopamine agonists including bromocriptine and cabergoline (3). Surgery and radiation therapy are reserved for patients unresponsive to medical therapy.

Adrenocorticotropic Hormone

ACTH is derived from a large precursor, pro-opiomelanocortin, which is cleaved by enzymatic action. Cleavage of the precursor also gives rise to melanocyte-stimulating hormone and opioid peptides. The main action of ACTH is on the renal cortex, stimulating release of glucocorticoids and androgens. Release of ACTH is stimulated by corticotropin-releasing hormone (CRH) release by hypothalamic CRH-producing cells in the median eminence. The action of CRH is potentiated by ADH. Inhibition of ACTH release is via a negative feedback loop where glucocorticoids detected at the level of the hypothalamus inhibit CRH release. Changes in osmolality and blood volume induced by ADH also have an inhibitory effect on CRH release. Secretory patterns follow a circadian rhythm with a nadir in the evening and a peak in the early morning. Secretion is pulsatile with up to 40 pulses per day. Amplitude rather than frequency of pulses determines the circadian rhythm. There is, however, a significant reserve in the system that can be mobilized in response to stress including infection, inflammation, and trauma.

Excess glucocorticoid production results in Cushingoid symptoms. Most commonly, Cushing's is a result of exogenous glucocorticoids but rarely can be caused by a pituitary adenoma. Up to 15% of pituitary adenomas are corticotroph adenomas. Some release excess ACTH resulting in Cushing's disease. However, a number of these are silent corticotroph adenomas, usually macroadenomas

with hemorrhage and mass effects including bone erosion (4). Treatment for these tumors is surgical with or without radiation therapy.

Gonadotrophs, Luteinizing Hormone, and Follicle-Stimulating Hormone

LH and FSH are homologous peptides that are released by the same cells of the anterior pituitary. They also share significant homology with TSH and bHCG. Each has a common alpha and distinct beta subunit. Posttranslational processing of carbohydrate side chains is also critical to hormonal signaling. The action of LH and FSH differs in males and females.

In females, LH stimulates cholesterol production for steroidogenesis in luteal cells of the ovary. It also enhances cytochrome P450–linked enzyme activity to synthesize pregnenolone and induces 3b-hydroxysteroid dehydrogenase, 17a hydroxylase, and 17,20 lyase activity. FSH regulates ovarian estrogen synthesis by inducing 17b hydroxysteroid dehydrogenase and aromatase. It also induces follicular growth, oocyte maturation, and androgen production. In males, Leydig cell LH receptors induce testicular testosterone production in response to LH. FSH may have a role in spermatozoa development.

Gonadotropin-releasing hormone release from the hypothalamus is pulsatile. The frequency and amplitude of the pulse determines the effect on LH and FSH secretion. The amplitude of the response is greater for LH than FSH. Generally, a decrease in pulse frequency induces LH secretion; an increase in pulse frequency induces a decrease in LH secretion. Inhibition is via a feedback mechanism. Testosterone inhibits LH and FSH release at both the hypothalamus and pituitary level. In fact, castration leads to an increase in gonadotropin levels. Gonadotropin release is also regulated by gonadal peptides inhibin A and B.

A deficiency in gonadotropins causes hypogonadism with decreased sex steroid production. If during childhood it is complete, there is a failure of male sexual development. In females it leads to amenorrhea. If partial, in males it leads to decreased libido, impotence, decreased fertility, and obesity. In females, partial deficiency leads to oligomenorrhea, vaginal dryness, hot flushes, decreased bone density, decreased breast tissue, and infertility.

Pituitary tumors of gonadotropin origin comprise about 15% of pituitary adenomas. Treatment is usually surgical but may be reserved for complications or impending complications since growth is variable. Stereotactic radiation may have a role for tumor control.

Thyroid-Stimulating Hormone

Thyrotrophs comprise approximately 5% of anterior pituitary cells. THS is a glycoprotein heterodimer composed of an alpha and beta subunit noncovalently linked. The beta subunit confers the specific action of TSH. The half-life of TSH is approximately 50 minutes. Its action is to stimulate thyroid follicle cells to synthesize and release thyroid hormone.

Stimulatory control occurs via thyroid-releasing hormone (TRH) released from the hypothalamus. Peak TSH levels occur approximately 30 minutes after TRH release. TRH stimulates both alpha and beta subunit transcription. Inhibition occurs through T3 feedback. T3 inhibits both alpha and beta subunit transcription. TSH release is also inhibited by dopamine, glucocorticoids, somatostatin, and some anti-inflammatory medications.

Thyrotroph cells of the anterior pituitary are developed by 12 weeks gestational age. TSH levels rise immediately after birth and remain elevated for about 5 days before reaching adult levels. TSH secretion also follows a circadian rhythm with a peak levels at 11 PM and 5 AM.

Deficiency of TSH in childhood leads to mental and growth retardation. In adults, it leads to hypothermia and fluid retention, along with voice, hair, and skin changes. Excess leads to palpitations, arrhythmias, weight loss, tremor, and nervousness.

Tumors of thyrotroph origin are rare and compose less than 1% of all pituitary adenomas. When they do occur, they are usually macroadenomas and often show bony erosion on presentation. Surgery is the primary treatment for these tumors. Radiation may be used as adjuvant therapy. Medical therapy is occasionally used and often involves octreotide, a somatostatin analogue. This is usually combined with symptomatic management that may include propylthiouracil (PTU), propranolol, and occasionally total thyroidectomy.

POSTERIOR PITUITARY

Antidiuretic Hormone

ADH, also known as vasopressin, is a nonapeptide with a six–amino acid chain connected by a cysteine–cysteine bridge to a three–amino acid tail. It is well conserved across mammalian species. Stimulation of the cell body in the hypothalamus leads to an action potential propagated along the axon to the nerve terminal in the posterior pituitary. This causes an influx of calcium and subsequent extravasation of neurosecretory granules. At any time, there is a 30- to 50-day basal supply stored in the neurosecretory granules. Its half-life is approximately 15 minutes.

ADH plays a critical role in water homeostasis and osmolality of body fluids. It plays a lesser role in blood pressure/volume control, which is controlled to a greater degree by the renin–angiotensin system. V1 receptors for ADH are found in blood vessel walls, V2 in renal collecting duct epithelium, and V3 receptors play a role in factor VIII production. High pressure/volume receptors in the carotid sinus and aortic arch along with low pressure/volume receptors in the atria and pulmonary venous system send afferent signals via cranial nerves IX and X to the

brain stem. Vagotomy results in increased ADH activity. ADH interaction with the V1 receptor leads to arterial and venous constriction. Interaction with the V2 receptor leads to water reabsorption resulting in decreased urine volume and increased urine concentration. Together, these effects lead to an increase in blood volume/pressure. Generally, decreased blood pressure/volume leads to ADH release, and increased blood pressure/volume inhibits ADH release.

Osmotic receptors in the hypothalamus respond to changes in blood osmolality. Osmolality is mainly a function of sodium concentration and is tightly controlled maintaining a range from 280 to 295 mOsm/kg H_2O. Basal ADH levels are 0.5 pg/mL. A 1% change in plasma osmolality will lead to a rapid release of ADH from secretory granules. There is a linear relationship between serum ADH levels and osmolality up to ADH levels of 6 pg/mL when maximum urine concentration is occurring.

Diabetes insipidus (DI) is defined by large volume, hypotonic dilute urine. The term insipidus means tasteless, as opposed to mellitus, which means sweet. There are three mechanisms that result in DI, so defined: (a) an inability to synthesize or secrete ADH, (b) nephrogenic—an inappropriate renal response to ADH—and (c) transient DI of pregnancy due to accelerated metabolism of ADH. A similar presentation can occur with excess water ingestion. This can be differentiated from an inability to synthesize or secrete ADH using serum sodium levels, which will be increased with hypothalamic DI and decreased in primary polydipsia. Hypothalamic DI may occur immediately after surgery in the region of the pituitary or hypothalamus (5). Patients ask for cold liquids and have large volume urine. More rarely, DI can be associated with craniopharyngiomas, pinealomas, and suprasellar germinomas. About 50% of DI is idiopathic.

Oxytocin

Oxytocin is the other hormone released from nerve terminals of the posterior pituitary. Release of oxytocin stimulates myometrial contraction at parturition. It also stimulates smooth muscle activity in the breast, promoting milk letdown with nursing. Release is mediated via mechanical and tactile receptors stimulated by suckling, leading to an afferent stimulus of the supraventricular and supraoptic nuclei. This causes a pulsatile release of oxytocin. At the end of pregnancy, parturition leads to a 200-fold increase in the responsiveness of myometrial cells to oxytocin.

PARATHYROID AND CALCIUM METABOLISM

The Parathyroid Glands

The parathyroid glands are derivatives of the third and fourth branchial pouches. The third pouch contains the primordia of the thymus and inferior parathyroid glands. The inferior parathyroids descend in the neck with the thymus typically reaching their destination in the anterior mediastinum at about the level of the inferior poles of their respective thyroid lobes. The fourth pouch gives rise to the superior parathyroid glands, which descend to their orthotopic position near the upper pole of the respective thyroid lobe. The fascia enveloping the thyroid gland can envelope the superior parathyroid glands as well. Even when the parathyroid glands are in their usual positions, the superior glands tend to be more posteromedial in position than the inferior glands. Supernumerary glands are not uncommon with up to 2.5% of the population having six glands. The normal adult weight for a parathyroid gland is 30 to 50 mg.

Ectopic locations for the parathyroid glands are not uncommon and reflect the direction and extent of descent during development. Superior glands can be found in the retro- or paraesophageal space and can be found in the posterior superior mediastinum. They can also be intrathyroidal (6). Inferior gland position is slightly more variable. Descent with the thymus leads to ectopic glands in the anterior superior mediastinum and even within the thymus. Up to one of three missed parathyroid adenomas will be found in the anterior mediastinum.

Blood supply to the parathyroid glands is usually via the inferior thyroid artery, but there are often multiple collaterals in the area. More rarely, the superior glands are supplied by the superior thyroid artery and the inferior gland by the inferior thyroid artery. Even more rarely, both glands are supplied by the superior thyroid artery. Venous drainage parallels arterial supply.

Parathyroid hormone (PTH) is an 84aa peptide cleaved from a larger precursor called pre-PTH. Its amino-terminal is the active portion of the hormone. It binds to receptors in bone and the kidney affecting an increase in serum calcium levels. In the kidney, receptor activation leads to an increase in $1,25(OH)_2D3$, the active form of vitamin D. In turn, vitamin D augments calcium absorption in the intestine as well as increasing the influx of calcium from bone and kidney. There is a small direct effect of PTH that causes an increase in calcium absorption in the cortical ascending loop of Henle but a more pronounced effect promoting calcium reabsorption from the distal convoluted tubule and the connecting tubule. Phosphate reabsorption in the proximal and distal tubules is strongly inhibited by PTH. In the bone, PTH has direct effects on osteoblasts and preosteoblasts. Osteoblast production of collagen is inhibited and maturation of preosteoblasts is inhibited. Effects on osteoclasts, or bone resorbing cells, are indirect via preosteoblasts and osteoblasts, which send cell signals to osteoclasts to mature, resorb bone, and inhibit apoptosis. Interestingly, constitutive PTH leads to bone resorption, but intermittent PTH favors an increase in bone mass. This has been used clinically. Teriparatide, an amino-terminal segment of PTH administered subcutaneously, is an FDA-approved treatment for severe osteoporosis.

Secretion of PTH is stimulated by a decrease in serum ionized calcium levels. Not only does PTH secretion vary inversely with ionized calcium levels but the PTH response for a given level of hypocalcemia is more dramatic if the rate of fall of ionized calcium is greater. Inactivation of the receptor for calcium through mutation is seen in familial hypocalciuric hypercalcemia. Chronic calcium receptor activation is also seen with genetic mutations and causes hypoparathyroidism with hypocalciuria. $1,25(OH)_2D3$ does not affect secretion of PTH. However, it does suppress PTH gene transcription. Increased phosphate levels stimulate PTH secretion indirectly by decreasing blood calcium and $1,25(OH)_2D3$ levels. Beyond the increased transcription and secretion of PTH, parathyroid cell number increases in the setting of hypocalcemia, low levels of $1,25(OH)_2D3$, hyperphosphatemia, and uremia. This is a slower response, and even if the underlying cause for the increased cell replication is no longer present, the resulting hyperparathyroidism can persist. This represents tertiary hyperparathyroidism.

Primary hyperparathyroidism is defined by the inappropriate hypersecretion of PTH. Seventy-five to eighty percent is caused by one or more adenoma, 20% by diffuse hyperplasia and <1% to 2% by parathyroid carcinoma. Carcinomas are usually associated with very high PTH levels and can be part of hyperparathyroidism–jaw tumor syndrome (parathyroid carcinoma and fibrous jaw tumors). Primary hyperparathyroidism is characterized by increased renal calcium absorption, phosphaturia, increased $1,25(OH)_2D3$, and increased bone resorption. The prevalence is thought to be approximately 0.04/1,000 population, but because many of those with primary hyperparathyroidism are asymptomatic, the numbers may be higher. DNA mutations including those of protooncogenes PRAD-1 and cyclin D1 have been implicated (7). There is some evidence that a remote history of neck irradiation may increase the risk. These mutations cause not only an increase in cell numbers but a decreased response of those cells to serum calcium levels. Parathyroid hyperplasia is seen in the MEN syndromes type 1 and 2a. In type 1 MEN, hypercalcemia is seen in 95% of patients and usually present in the second or third decade of life. In type 2a MEN, only 5% to 20% of patients manifest symptoms of hyperparathyroidism.

The natural history of asymptomatic primary hyperparathyroidism is uncertain, although there is evidence of increased fracture risk (8). Current indications for surgery are controversial but include those (a) <50 years of age, (b) who cannot participate in appropriate follow-up, (c) with a serum calcium level >1.0 mg/dL above the normal range, (d) with urinary calcium >400 mg/24 h, (e) with a 30% decrease in renal function, or (f) with complications of primary hyperparathyroidism, including nephrocalcinosis, osteoporosis (*T*-score <2.5 SD at the lumbar spine, hip, or wrist), or a severe psychoneurologic disorder (9). Medical management for the remaining asymptomatic hyperparathyroid patients includes semiannual clinical evaluations, avoidance of diuretics and immobility, maintenance of adequate hydration, and limiting oral calcium to 800 mg/day. Symptomatic patients have combinations of decreased cortical bone, hypercalciuria associated with nephrolithiasis, and even renal failure, flank pain, polyuria/polydipsia, conjunctival calcifications, GI symptoms, and pathology that may include pancreatitis, neuropsychiatric problems, and neuromuscular complaints. Although symptoms can sometimes be difficult to directly attribute to hyperparathyroidism, the recommendation for symptomatic patients is for surgery unless it is otherwise contraindicated. In those patients that cannot undergo surgery, bisphosphonates like alendronate can improve bone density but have minimal effects on serum calcium and PTH. Calcimimetics like cinacalcet can lower serum calcium and PTH but do not affect bone density.

Secondary hyperparathyroidism is defined by the appropriate hypersecretion of PTH. It can be seen with decreased serum calcium levels secondary to excess urinary loss, or inadequate intake, hypophosphaturia due to aluminum poisoning, kidney disease and decrease calcium levels, and decreased $1,25(OH)_2D3$ levels secondary to decreased sunlight exposure or malnutrition. Treatment is directed by the underlying cause.

Calcitonin

Calcitonin is a 32aa polypeptide with a disulfide bridge. Although it is an important component of calcium metabolism in many species, its importance in humans remains uncertain. It is secreted by intrathyroidal C-cells of neural crest origin. It is incorporated into the thyroid gland as the ultimobranchial bodies (the primordia of the C-cells) merge with the developing thyroid. In other species, calcitonin causes a decrease in tubular resorption of calcium in the kidneys and decreases osteoclast-mediated bone resorption. However, in humans, thyroidectomy has no significant effect on bone density and even high-dose exogenous calcitonin has minimal long-term effects (10).

Secretion of calcitonin is closely related to serum calcium levels. C-cells have the same calcium receptor as parathyroid chief cells, and increased calcium levels cause an increase in calcitonin secretion. There are a number of gastrointestinal hormones that stimulate calcitonin secretion as well. Their role in calcium regulation is uncertain. Inhibition is through somatostatin via an autocrine secretion. Transcription for calcitonin in C-cells is inhibited by $1,25(OH)_2D3$.

Vitamin D

With sun exposure (UV radiation), the cutaneous precursor of vitamin D, 1,7dehydrocholesterol, undergoes cleavage to form a thermally labile product that subsequently undergoes a rearrangement to form vitamin D. Excess sun

exposure leads to alternative rearrangement leading to biologically inert products. Subsequently, the precursor product undergoes a 25 hydroxylation, which occurs in the liver. This is followed by 1-alpha hydroxylation in the proximal convoluted tubule of the kidney. 1-Alpha hydroxylase activity is stimulated by PTH and hypophosphatemia. The product of this hydroxylation has an inhibitory effect on 1-alpha hydroxylase. The final product $1,25(OH)_2D3$ has a half-life of 6 to 8 hours. Vitamin D is also obtained through the diet. Fortified dairy products and cereal, egg yolks, and fish oil are major sources.

Vitamin D binds to nuclear receptors found in most tissues. Vitamin D precursors have an affinity but a much lesser affinity for the same receptors. Although present in most tissues, receptor binding has its greatest effect in the intestine. Receptors in the jejunum and duodenum, when bound, induce calcium channels important for intestinal absorption of calcium. A normal diet contains 700 to 900 mg of calcium. Typically, 30% to 35% is absorbed. Vitamin D effects on bone include increased differentiation of osteoclasts and osteoclast-mediated bone resorption.

Hypercalcemic Crisis

There are many conditions that can cause hypercalcemia. The two most common etiologies are primary hyperparathyroidism and malignancy. Together, they account for about 90% of all cases. In the hospital setting, malignancy is often the underlying culprit in hypercalcemia. In the outpatient clinic, primary hyperparathyroidism is the dominant etiology for chronic asymptomatic hypercalcemia. Hypercalcemic crises are the result of severely elevated calcium levels due to any cause, malignancy being the most common, and are associated with a significant mortality rate. Calcium levels between 13 and 15 mg/dL require aggressive treatment, while levels above 15 mg/dL can be life threatening and demand emergent therapy. The severity of symptoms is related to not only the absolute calcium level but also the rate of calcium level elevation. Hypercalcemia due to malignancy carries a poor prognosis as life expectancy is generally less than 6 months when hypercalcemia develops. Patients often present with acute mental status changes, confusion, bone or muscle pain, constipation, and fatigue. On examination, they appear to be dehydrated, with varying degree of mental status change. Laboratory evaluation invariably demonstrates elevated calcium levels with low, normal, or elevated PTH levels depending on the etiology. Hypercalcemia may be accompanied by acute renal insufficiency.

The pathogenesis of hypercalcemia is mediated through 3 different mechanisms. It can be due to elevated PTH, which activates osteoclasts and bone resorption, increases calcium absorption from the gastrointestinal tract, as well as reducing calcium excretion in the urine. This is the underlying mechanism of hypercalcemia occurring in primary hyperparathyroidism. Hypercalcemia can also be due to elevated parathyroid hormone–like protein (PTHrP) in patients with squamous cell carcinoma of the lung, head and neck, cervix, esophagus, vulva, and skin, as well as breast cancer, renal cell, and bladder cancer. PTHrP has similar functions to PTH and occupies the same receptors, but its secretion is not regulated by calcium level. The third mechanism is through lymphokines or cytokines such as TNF-beta, IL-1, lymphotoxin, or $1,25\ (OH)_2D$ released locally by tumor cells. These factors act on osteoblasts to stimulate bone resorption and cause hypercalcemia. This occurs often in patients with breast cancer or any cancer with metastasis to the bone or hematogenous tumors such as multiple myeloma, leukemia, and lymphoma.

The treatment of hypercalcemia includes aggressive IV hydration, judicious use of diuretics, bisphosphonates, calcitonin, and steroids. This combination approach can decrease serum calcium by 3 to 9 mg/dL within 24 to 48 hours in most patients, enough to relieve acute symptoms, prevent death from hypercalcemic crisis, and permit diagnostic evaluation. In a patient with hypercalcemic crisis, the critical first step in treatment is hydration. Patients are invariably dehydrated due to vomiting, poor intake, and a decreased ability to concentrate the urine induced by hypercalcemia. Rehydration with IV normal saline should be given as a bolus of 1 to 2 L initially, then at 200 mL/h for the first 24 hours in patients without a history of congestive heart failure. Subsequently, IV normal saline can be given at 100 mL/h until fluid status is replete. Care should be taken to prevent magnesium and potassium depletion. Loop diuretics such as furosemide can be given to patients to hasten calcium excretion only in the setting of adequate rehydration. Diuretics given too early in a dehydrated hypercalcemic patient may worsen hypercalcemia and renal insufficiency.

Calcitonin inhibits osteoclast action through receptors on the osteoclast. It also increases renal calcium excretion by inhibiting renal tubular calcium reabsorption. Therefore, it is a very effective agent within the first 24 hours of treatment of hypercalcemia as it can reduce calcium level within hours. However, its effect is short lasting secondary to tachyphylaxis, and it should not be used beyond the first 48 hours of treatment. The other benefit of calcitonin is that it has anesthetic effects, which can relieve the severe bone pain associated with hypercalcemia.

Bisphosphonates are the mainstay of treatment to lower calcium levels. Bisphosphonates are analogues of pyrophosphate, with a high affinity for bone, and reduce calcium levels by inhibiting osteoclast action, therefore suppressing bone resorption. This effect, however, takes 3 to 6 days to become effective and therefore cannot acutely lower calcium levels. Either pamidronate 30 to 90 mg or zoledronic acid 1 to 4 mg can be given intravenously to patient with hypercalcemia. Dose reduction is generally recommended in the setting of renal insufficiency. Repeat therapy as frequently as every month is necessary in patients with recurrent hypercalcemia due to malignancy.

Glucocorticoids can be helpful in hypercalcemia due to some malignancies. They increase urinary calcium excretion and decrease intestinal calcium absorption when given in pharmacologic doses. They are especially useful in those osteolytic malignancies such as multiple myeloma, leukemia, Hodgkin disease, other lymphomas, and carcinoma of the breast. They are also effective in treating hypercalcemia due to vitamin D intoxication and granulomatous disease such as sarcoidosis.

Other agents such as gallium nitrate and plicamycin are not used often nowadays, given their toxicity and better alternative therapies. Occasionally, dialysis may be needed in patients who have renal failure and hypercalcemia.

Hypocalcemia

Acute hypocalcemia generally occurs as a result of hypoparathyroidism due to thyroid or parathyroid surgery. Sometimes, it is caused by "hungry bone" syndrome experienced by patients postoperatively following surgery for a large parathyroid adenoma. Occasionally, other anions such as citrate, bicarbonate, or phosphate may complex with ionized calcium to decrease its concentration precipitously. The symptoms of hypocalcemia correlate closely with the rate of decrease in calcium levels but not necessarily with the absolute calcium level. Patients with chronic hypocalcemia generally tolerate the low levels of calcium quite well without significant symptoms. However, for those patients with hypocalcemia after thyroid or parathyroid surgery, the symptoms can be quite pronounced. Patients often have numbness and paresthesias, especially around their mouth and nose tip. Muscle spasm, carpopedal spasm, and facial grimacing can occur as well. Laryngeal spasm, convulsions, respiratory arrest, and cardiac arrhythmias can result in mortality if not treated immediately. Patients sometimes have increased irritability, depression, or psychosis. On examination, muscular hyperactivity can be demonstrated with Chvostek sign or Trousseau test. Treatment of hypocalcemia includes oral or IV calcium. To acutely increase calcium level in a symptomatic patient, 20 mL of calcium gluconate (180 mg elementary calcium) can be given over a 10-minute period. This is followed by infusion of 60 mL of calcium gluconate in 500 mL of D5W over 4 to 6 hours (12). Concurrent magnesium deficiency must be treated as well. Calcium given intravenously has a very short half-life, and therefore, calcium levels go down quickly once IV calcium is discontinued. Once oral intake resumes, patients can take either oral calcium carbonate or calcium citrate at doses of 1 to 2 g of elementary calcium three times per day. The dose is adjusted based on calcium levels. Calcium citrate is preferred in those with a history gastric reflux disease and on antiacid treatment as calcium is better absorbed in an acidic environment. Calcium carbonate is better taken with meals based on the same principle. Calcium should be given in divided doses as there is a limit to intestinal absorption at any given time. Calcium is mostly absorbed in the duodenum and proximal jejunum. The active transportation of calcium relies on the calcium transporter, and vitamin D increases the active transportation of calcium. To increase calcium absorption in patients with permanent hypoparathyroidism, calcitriol in a dose of 0.25 to 1 mcg/day is often necessary. The goal of treatment is to maintain calcium level between 8 and 8.8 mg/dL to avoid hyperphosphatemia given calcitriol increases both calcium and phosphate absorption. Long-term treatment of hypocalcemia aims to relieve symptoms and to avoid hyperphosphatemia or hypercalciuria. Hydrochlorothiazide can be used in difficult cases to reduce calcium excretion in the urine and stabilize the calcium level.

THYROID

The thyroid gland develops by the third week of gestational life, and thyroid hormone synthesis begins at about 11 weeks gestation. The thyroid gland secretes two related hormones, triiodothyronine (T3) and thyroxine (T4). These hormones bind to nuclear receptors in multiple organ systems and alter the transcriptions of numerous genes. They regulate cell differentiation during development and maintain thermogenic and metabolic homeostasis in the adult.

Thyroid hormone is synthesized in the thyroid follicular cells. Normally, thyroid follicular cells surround secreted colloid to form follicles. The basolateral side of follicular cells apposes the blood stream, and the apical side of the follicular cells faces the follicular lumen. The colloid is made of thyroglobulin (Tg), the protein precursor of thyroid hormones. The first step in thyroid hormone synthesis is iodide uptake. Iodide uptake into the follicular cell is regulated by sodium iodide symporter at the basolateral side, and efflux into the lumen is controlled by a protein called pendrin located on the apical side. Once iodide enters the follicular cells, it translocates to the apical membrane of thyroid follicular cells where it is oxidized. This organification reaction requires thyroid peroxidase (TPO) and hydrogen peroxide. The reactive iodine atom is then added to selected tyrosyl residues within Tg. Coupling of the iodotyrosines in Tg occurs through an ether linkage mediated by TPO. Either T3 or T4 can be produced depending on available iodine atoms in the iodotyrosines. After coupling, Tg is taken back into the thyroid cells and processed in lysosomes subsequently releasing T4 and T3 into blood stream. Uncoupled mono- and diiodotyrosines are deiodinated to recycle any iodide that is not converted into thyroid hormones.

Thyroid hormone synthesis is regulated by TSH secreted by anterior pituitary thyrotrophs and TRH produced by the hypothalamus. TRH and TSH positively stimulate thyroid hormone synthesis and production. On the other hand, thyroid hormones negatively regulate TRH and TSH production. In thyrotoxicosis, the excessive thyroid hormone directly downregulates TSH secretion and inhibits TRH-mediated

stimulation of TSH. On the contrary, in hypothyroidism, inadequate thyroid hormones stimulate TSH secretion as well as enhance TRH-mediated stimulation of TSH to increase thyroid hormone and maintain homeostasis. Iodine can also affect thyroid hormone synthesis. In iodine deficient areas, compensatory enlargement of the thyroid gland is commonly seen. Iodine excess can temporarily lead to decrease in thyroid hormone synthesis; this is called the Wolff-Chaikoff phenomenon. However, in 2 to 3 weeks, a normal functioning gland will escape this phenomenon and resume thyroid hormone synthesis. Patients with underlying autoimmune thyroid disease often cannot escape this phenomenon, and chronic iodine overload leads to hypothyroidism. Besides TSH and iodide, IGF-1, epidermal growth factor, transforming growth factor beta, endothelin, and various cytokine can influence thyroid hormone synthesis and release.

The thyroid gland releases 20-fold more T4 into the circulation than T3. Both T3 and T4 are bound to thyroxine-binding globulin, transthyretin, and albumin. Overall, about 99.98% of T4 and 99.7% of T3 is protein bound. Only free hormone is active. Because of the lower binding affinity for T3 compared to T4, there is more free T3. T4 is converted into T3 peripherally by type 1 or type 2 deiodinase. T4 is converted to reverse T3, an inactive thyroid hormone by type 3 deiodinase. Illness, fasting, acute trauma, and a variety of medications (PTU, propranolol, amiodarone, and glucocorticoids) inhibit T4 conversion to T3 but increases T4 conversion to rT3 (11).

Thyroid hormones exert biologic effects by binding to their nuclear thyroid hormone receptors alpha and beta. Both T3 and T4 bind thyroid hormone receptors but the affinity is 10 to 15 times higher for T3 compared to T4, and therefore, T3 is much more biologically active. The nuclear receptors are made of a central DNA-binding domain and a C-terminal ligand-binding domain. These receptors bind to specific DNA sequences called thyroid response elements in the promoter regions of target genes. Binding to some of the thyroid response elements leads to inhibition of gene transcription while in others leads to stimulation of gene transcription. This explains the diverse effects of thyroid hormones on multiple gene transcription.

Thyroid Storm

Thyroid storm is an extreme of hyperthyroidism. The mortality rate due to cardiac failure, arrhythmia, or hyperthermia is as high as 30% even with treatment (12). Thyroid storm most often occurs in patients with Graves disease, although it can occur in patients with toxic multinodular goiter. Patients often have untreated or inadequately treated hyperthyroidism. It is frequently brought on by another medical condition, such as acute illness (stroke, infections, DKA, preeclampsia, parturition), trauma, surgery (especially on the thyroid), or radioactive iodine treatment, which leads to an acceleration or decompensation of the hyperthyroid state.

Patients present with an exacerbation of hyperthyroidism manifested by fever, delirium, high-output heart failure, diarrhea, vomiting, irritation, confusion, coma, or jaundice. On examination, there is a widened pulse pressure, sinus tachycardia or arrhythmia, an enlarged thyroid gland, tachypnea, and hyperthermia. It is a hyperadrenergic condition. Laboratory evaluation often shows suppressed TSH and elevated fT3 and fT4. The level of elevation of thyroid hormone does not necessarily correlate with the occurrence of thyroid storm. Liver function tests and alkaline phosphatase may be slightly abnormal as well. The diagnosis of thyroid storm is based on history and physical examination, and a scoring system has been developed that may be useful in management (12).

The management of thyroid storm includes maintaining adequate circulatory volumes, reducing thyroid hormone synthesis, reducing T4 conversion to T3, and supportive therapy. To reduce thyroid hormone synthesis, either methimazole or PTU can be used. PTU has the additional advantage of inhibiting T4 conversion to T3, the most active form of thyroid hormone and therefore is the preferred agent for patients in thyroid storm. Patient in thyroid storm generally requires a high dose of PTU; the dose often needs to be at 200 to 300 mg every 4 to 6 hours to be effective. A 600-mg loading dose should be given first. Once the clinical condition improves, the PTU dose can be reduced or switched to methimazole. Methimazole has the advantage of a longer half-life and therefore can be given once per day to improve compliance. When oral intake is not possible, PTU or methimazole can be given rectally. To reduce thyroid iodide organification via the Wolff-Chaikoff phenomenon, potassium iodide (at five drops every 6 hours) or iopanoic acid (0.5 mg every 12 hours) may be given orally 1 hour after the first dose of PTU (12). The delay after PTU permits inhibition of iodine incorporation into newly synthesized thyroid hormone. Excessive iodide transiently inhibits thyroid iodide organification and therefore reduces thyroid hormone synthesis. This effect, however, does not last more than 2 to 3 weeks, and beyond that time, escape develops and thyroid iodide organification resumes. Therefore, this is only a temporizing measure before a more permanent treatment solution such as surgery or radioactive iodine can be instituted. The benefit of using iodide in thyroid storm is that it allows time for either methimazole or PTU to become effective. To reduce the hyperadrenergic state, beta-adrenergic blocking agents, including propranolol, atenolol, or metoprolol can be used. Propranolol is the preferred agent because it is a nonselective beta receptor blocker and at higher doses inhibits T4 to T3 conversion. It can be given 1 to 2 mg IV every 4 to 6 hours when oral intake is in question or orally at 40 to 60 mg every 4 to 6 hours. For patients with a history of asthma or obstructive lung disease or heart failure, a selective beta1 blocker like atenolol is a better agent to use. Glucocorticoids suppress conversion of T4 to T3 and therefore can also be used in patients in storm to reduce

active thyroid hormone levels. It should also be used if there is hypotension present to treat possible coexisting relative adrenal insufficiency. Glucocorticoids can be given as prednisone 60 mg/day or dexamethasone 1 to 2 mg/day. Besides these measures, supportive therapy is important. For hyperthermia, a cooling blanket can be used. Care should be taken to prevent a precipitous temperature decline. If blood pressure is low, volume expansion with normal saline and pressors may be needed to support the circulation. Cardiac arrhythmias may require pharmacotherapy and anticoagulation. The underlying cause needs to be aggressively sought and treated to avoid additional morbidity.

Myxedema Coma

Myxedema coma is another extreme of thyroid dysfunction. It has a high mortality rate despite treatment. Any cause of hypothyroidism can lead to myxedema coma. A typical patient with myxedema coma is an elderly female with a history of long-standing hypothyroidism not being treated or treated inadequately. There is almost always a precipitating factor such as underlying infection (pneumonia, urinary tract infection), medications (e.g., sedatives, anesthetics, antidepressants)), congestive heart failure, myocardial infarction, gastrointestinal bleeding, cerebrovascular accidents, poor oral intake, cold exposure, or an exacerbation of another chronic illness. Symptoms develop insidiously often delaying diagnosis. Patients present with hypothermia, hypoventilation, confusion, and/or coma. Physical examination reveals a confused patient with hypothermia, bradycardia, yellow-tinged skin, periorbital edema, dry skin, and nonpitting peripheral edema. Laboratory testing reveals elevated TSH and decreased fT4. Early diagnosis is essential in reducing mortality and morbidity.

The treatment of myxedema coma is to supplement thyroid hormone, maintain circulation, support respiratory system, and treat the underlying etiology. The precipitating factor needs to be aggressively sought. If found, it should be treated appropriately. Unfortunately, the underlying cause cannot always be found. To replace thyroid hormone, intravenous levothyroxine at a dosage of 300 to 500 mcg should be given as a loading dose as it can saturate the thyroid hormone receptors in different tissues. Subsequently, 50 to 100 mcg IV can be given once per day. Once the clinical condition improves, levothyroxine can be given orally. The advantage of using the intravenous form of levothyroxine is that it bypasses the GI tract to eliminate the effects of malabsorption resulting from bowel edema in a severely hypothyroid patient. For those with a history of heart disease, thyroid hormone dose reduction is often necessary to prevent acute MI or decompensation of myocardial function. Before treatment with levothyroxine, adrenal insufficiency often needs to be ruled out. In a patient with concurrent adrenal insufficiency, use of levothyroxine can precipitate an adrenal crisis. Patients with myxedema coma have impaired adrenal reserve and hydrocortisone 50 mg IV q6h is often necessary. It can be quickly tapered once the clinical condition improves. Supportive therapy in a myxedema coma patient is essential. Warming blankets can be used to slowly increase temperature, but care should be taken to avoid increasing the temperature to normal too quickly and should be used only if the temperature is below 30 degrees. Patients in myxedema coma often develop constricted peripheral vasculature to maintain their blood pressure. Increases in body temperature can lead to peripheral artery dilatation and result in rapid collapse of the circulation. For patients who are hypotensive, volume expansion with isotonic crystalloids or whole blood and judicious pressor use is often necessary to maintain adequate blood pressure. Glucose is necessary if there is hypoglycemia. Hypotonic fluids should be avoided because they may exacerbate water retention secondary to reduced renal perfusion and inappropriate vasopressin secretion. Sedatives should be avoided or used at reduced doses because the metabolism of most medications is impeded. Respiratory support with mechanical ventilation is often necessary and may be prolonged. If there is underlying infection, broad-spectrum antibiotics should be empirically used while waiting for blood culture and drug sensitivity results to come back. Myxedema coma has a very high mortality rate. It requires aggressive treatment if positive outcomes are to be achieved.

ADRENAL GLANDS

The adrenal gland is composed of the cortex and the medulla. The medulla is made of chromaffin cells that secrete catecholamines and their metabolites that alter heart rate, blood pressure, vascular tone, and carbohydrate metabolism. The cortex consists of three different layers. The outermost layer, the zona glomerulosa, secretes mineralocorticoid aldosterone, which regulates blood pressure, vascular volume, and Na and K metabolism. The middle layer zona fasciculata secretes glucocorticoids, which regulate immune response and stress response as well as modulating intermediary metabolism. The glucocorticoids are bound to cortisol-binding globulin and albumin. Only the free form is the biologically active form, which is less than 5% of all cortisol. The innermost layer zona reticularis produces adrenal androgen dehydroepiandrosterone, which is important for secondary sexual characteristics in females. A variety of adrenal disorders occur as a result of over or under functioning of each of the individual layers. The most common diseases are discussed in the following sections.

Primary Aldosteronism

Primary aldosteronism is due to an adenoma or hyperplasia of the outer layer of the adrenal cortex. Overproduction of aldosterone leads to hypertension and hypokalemia,

hallmark features of the disease. About 1% of patients with hypertension have primary aldosteronism. The mortality rates of patients with primary aldosteronism are slightly higher than those without it. This is thought to be due to aldosterone's effect on the cardiovascular system independent of its effect on blood pressure. Symptoms of primary aldosteronism include headaches, muscle weakness, fatigue, nocturnal polyuria, or cramping. Patients characteristically do not have edema and have diastolic hypertension. Laboratory evaluation shows normal or high normal sodium level, hypokalemia, metabolic alkalosis, suppressed renin, and elevated aldosterone level. A normal potassium level does not exclude primary aldosteronism. The screening test for this disease involves measurement of the aldosterone/renin ratio. If the ratio is above 25, further confirmatory tests are necessary. A salt loading test with measurement of the 24-hour urine aldosterone level during the last 24 hours of a 72 hours test can either confirm or exclude the diagnosis. During this test, adequate salt intake is necessary and can be achieved by giving patients NaCl tablets 2 g three times per day. A 24-hour urinary sodium level should be measured to verify adequate salt intake during the test. Once hyperaldosteronism is confirmed, imaging such as CT of the adrenal gland can to be pursued. Aldosterone-secreting adenomas can be tiny, and therefore, a dedicated fine-cut CT is often necessary to visualize the adenoma. For patients younger than age of 40, identification of a unilateral adenoma combined with biochemical evidence of hyperaldosteronism is adequate to recommend unilateral adrenalectomy. For those who are older than 40, even with the identification of a unilateral adenoma (given increased incidence of benign nonfunctioning adrenal adenoma), and for those without a distinct adenoma on either side, further lateralization studies such as adrenal vein sampling is necessary. Treatment for primary aldosteronism includes surgery or medical therapy. Surgery is preferred for younger patients with unilateral adenoma. For older patients or patients with bilateral adrenal hyperplasia, treatment with spironolactone, triamterene, or amiloride can achieve good control of blood pressure and potassium levels. With adequate control, patients with primary aldosteronism achieve excellent outcomes (13).

Secondary Aldosteronism

Secondary aldosteronism is due to normal activation of the renin–angiotensin system in response to hypertension or any edema disorders such as cirrhosis or congestive heart failure. There is secondary overproduction of renin due to decreased renal perfusion pressure or renal blood flow rather than primary overproduction of renin due to a renin-producing tumor. The laboratory evaluation for secondary aldosteronism demonstrates both elevated renin and aldosterone, which distinguishes it from primary aldosteronism. Treatment for secondary aldosteronism is to correct the underlying etiology.

Adrenal Insufficiency

Adrenal insufficiency can be due to primary or secondary causes. All primary causes result in the destruction of the adrenal glands bilaterally and subsequent adrenal insufficiency. Common etiologies are autoimmune adrenalitis, chronic granulomatous disease (predominantly tuberculosis), bilateral adrenalectomy, bilateral adrenal gland metastases, thrombosis, hemorrhage, and viral or fungal infections. Secondary adrenal insufficiency is due to suppression by chronic exogenous steroids or occurs as a result of pituitary insufficiency leading to inadequate ACTH production. Patients generally present with insidious onset of malaise, weakness, nausea, vomiting, abdominal pain, dizziness, poor appetite, weight loss, hypotension, and occasionally hypoglycemia. Hyperpigmentation occurs in those with primary adrenal insufficiency. If not recognized, adrenal crisis can happen in patients undergoing surgery, experiencing trauma, or having concurrent infections. Laboratory testing demonstrates no abnormality at the mild stage but with persistent progression of disease, shows hyponatremia, hyperkalemia, and decreased chloride and bicarbonate levels. The diagnosis is made with a cosyntropin stimulation test, which is performed by administrating 250 mcg of cosyntropin and measuring cortisol level 30 and 60 minutes afterward (14). Treatment is directed at adrenal hormone replacement. It can be achieved with either hydrocortisone 20 to 30 mg in 2 divided doses given 2/3 in the morning and 1/3 around 4 PM or prednisone 5 to 7.5 mg once per day in the morning. Patients with primary adrenal insufficiency require replacement of mineralocorticoids in the form of fludrocortisones 0.1 to 0.2 mg/day. All patients with adrenal insufficiency should carry medical identification and should be instructed to self-administer parental glucocorticoids when oral intake is not possible. Patients will need to double or triple steroid dose during periods of other intercurrent illness. During trauma or surgery, the stress dose of hydrocortisone at 50 to 100 mg three times daily should be given initially then tapered quickly to home steroid dose guided by clinical response.

Acute adrenal insufficiency can be due to acute hemorrhagic destruction of adrenal glands secondary to pseudomonas or meningococcemia, anticoagulant therapy or a coagulation disorder, or rapid withdrawal of steroid in patients with chronic steroid use. During adrenal crisis, the stress dose of steroid is administered. Pressor support along with other supportive therapy such as sodium and water replacement is essential as adrenal crisis has a high mortality rate.

Cushing's Syndrome

Cushing's syndrome is a result of excessive glucocorticoid. It could be due to adrenal adenoma, adrenal carcinoma, adrenal hyperplasia, pituitary adenoma, exogenous glucocorticoid treatment, or ectopic ACTH/CRH sources such

as lung, thymus, or pancreatic tumors (15). Patients often present with weight gain, emotional liability, fatigability, easy bruises, paroxysmal muscle weakness, amenorrhea, hirsutism, frequent infection, and osteoporosis. On physical examination, key features are truncal obesity; hypertension; moon facies; supraclavicular fat pad; buffalo hump; violaceous striae of the abdomen, hips, and breast; and thin skin. To diagnose Cushing's disease, hypercortisolism needs to be demonstrated by an increased 24-hour urine cortisol, increased midnight salivary cortisol, or an abnormal 1-mg-dexamethasone suppression test. To further confirm hypercortisolism, a 2-day low-dose dexamethasone suppression test can be pursued. If results are abnormal, the etiology of hypercortisolism can be determined by measuring ACTH levels or performing a high-dose dexamethasone suppression test. Patients with adrenal Cushing's disease often have low or suppressed ACTH, while those with pituitary Cushing's disease frequently have normal or high ACTH levels. Patients with ectopic Cushing's syndrome resulting from lung cancer or lung carcinoids invariably have a very elevated ACTH level. The high-dose dexamethasone test is helpful to distinguish between pituitary versus nonpituitary Cushing's disease. Only patients with pituitary disease will have a suppressed result on the high-dose dexamethasone test. Tumor localization can be achieved with CT of the adrenals for adrenal causes, MRI of the pituitary gland for pituitary pathology, or CT of the chest and abdominal for ectopic sources. The primary treatment for Cushing's disease is surgery. Medical therapy is limited and includes ketoconazole, mitotane, metyrapone, and other agents. These treatments are useful when surgery is not possible. After surgery, replacement therapy with glucocorticoids is often necessary given patients often have transient adrenal insufficiency. The dose of steroid should be tapered off slowly in 6 months to 1 year. Some patients may require a taper taking more than 1 year. During the taper process, stress dose steroid should be used in times of surgery, sickness, or trauma. Adrenocortical cancer is rare but has a poor prognosis. Surgery is the mainstay of treatment. Radiation or adjuvant chemotherapy with mitotane or other agents can be used.

Pheochromocytoma

Pheochromocytoma is a tumor of adrenal or extra-adrenal chromaffin cells. It is unilateral in sporadic cases but may be multilateral, especially in familial cases. The majority of pheochromocytomas are benign. Ten percent of them are malignant. Pheochromocytomas are present in about 0.1% of hypertensive patients and are often fatal if undiagnosed or mistreated. The clinical features are mostly related to the release of catecholamines. Classic presentation includes episodic hypertension, palpitation, and cold sweats. Over half of the patients can have hypertensive paroxysms or crises, which can be alarming and resistant to treatment. However, some patients present with chronic hypertension and never have an episodic symptom. Laboratory evaluation demonstrates elevated 24-hour urine metanephrines or plasma metanephrines. CT or MRI of the adrenals often identifies the tumor. Functional studies with an MIBG scan may be necessary when biochemical evaluation is indeterminate or metastasis is suspected or the adrenal lesion is more than 5 cm. Treatment for pheochromocytoma is surgery. Pheochromocytomas can have devastating consequences intraoperatively, and treatment with α-adrenergic blocker should be instituted before addition of beta-adrenergic blockers. Phenoxybenzamine can be started at 10 mg bid and titrated up to 30 mg tid depending on blood pressure response. Volume expansion is essential to reduce positional hypotension. This can be easily achieved with adequate fluid intake along with a high salt diet. Other medications such as prazosin, calcium channel blockers, and angiotensin-converting enzyme inhibitors are alternative blood pressure management agents if patients could not tolerate phenoxybenzamine. Beta blockers such as propranolol at 10 mg three to four times per day are useful for tachycardia. After complete resection, catecholamine levels return to normal 2 weeks after surgery, and 75% of patients have a cure of their hypertension. Lifelong follow-up of pheochromocytoma is necessary given the low albeit still present chance of recurrence.

THE PANCREAS AND GLUCOSE METABOLISM

Glucose, a monosaccharide, is an absolute requirement for neuronal survival. For that reason, glucose homeostasis and its control via pancreatic hormones is critical. Insulin and glucagon are the primary regulators of glucose metabolism in the body. Carbohydrates in their various forms are first ingested. In the gut they are, for the most part, broken down into monosaccharides, mainly glucose. There, glucose is absorbed via the GLUT family of transporters into cells of the gut. What is not immediately used is stored. In the liver and muscle, it is stored as glycogen. It is also converted into fatty acids, which are eventually incorporated into triglycerides in adipose tissue. Through a variety of mechanisms, the liver is also an important organ in the control of blood glucose levels.

The liver, muscle, and adipose tissue all possess insulin receptors. In the liver, insulin promotes glycogen synthesis and inhibits glycogen phosphorylation. It does not affect glucose uptake in the liver. In muscle and adipose tissue, insulin induces rapid uptake of glucose by recruiting GLUT transporters. Subsequently, muscle converts glucose to glycogen, and in adipose tissue, glucose is converted to fatty acids. Insulin also increases uptake of amino acids into muscle. It suppresses breakdown of glycogen in both muscle and liver and inhibits release of amino acids from muscle and fatty acids from adipose tissue.

Glucagon has opposing actions to insulin. It binds to a G-protein-linked glucagon receptor that stimulates cAMP.

Its eventual action includes the breakdown of glycogen into glucose, production of glucose from amino acids, and the release of fatty acids from adipose tissue, which are eventually converted into ketoacids in the liver.

The absorptive state of an individual relative to carbohydrate ingestion determines insulin/glucagon ratios.

Insulin

Insulin is a 51–amino acid protein with significant homology to insulin-like growth factor 1 and 2. Synthesis occurs in the beta islet cells of the pancreas. Initial synthesis forms preproinsulin and includes a signal peptide, along with A and B chains connected by a polypeptide. The signal peptide is quickly cleaved as is the connecting peptide, and eventually, the A and B chains form the active product.

Secretion of insulin is pulsatile, typically at 10-minute intervals. The half-life of insulin is approximately 3 minutes. Fifty percent of synthesized insulin is taken up by the liver in what is termed the "first-pass" effect. The remainder has effects on the peripheral tissues. Secretion is stimulated by a number of factors. Both plasma glucose and amino acids stimulate insulin secretion, and their effects are synergistic. Triglycerides and free fatty acids have a lesser stimulatory effect. A number of gastrointestinal hormones and GH also stimulate secretion. Cholinergic and alpha-adrenergic neurons of the autonomic nervous system stimulate insulin secretion as well. Secretion occurs in two phases: there is an initial release of insulin stored in secretory granules followed by a more gradual and stable release in response to *de novo* synthesis. Suppression of insulin secretion occurs via adrenaline and cortisol as well as beta-adrenergic neurons of the autonomic nervous system.

Glucagon

Glucagon is a 29-aa protein initially synthesized as proglucagon in the alpha cells of the pancreas. A signal peptide is cleaved to form glucagon and other by-products. The half-life of glucagon is approximately 3 minutes. Like insulin, approximately 50% of secreted glucagon is taken up by the liver in what is termed the "first-pass" effect.

Glucagon secretion is stimulated by low glucose levels and protein meals if they are high in alanine and arginine. GH and adrenaline are other hormones that stimulate glucagon secretion. Secretion is also stimulated by exercise, stress, and starvation. Secretion is suppressed by insulin and glucose and to a lesser degree by somatostatin.

Diabetes Mellitus

Diabetes mellitus (DM) is defined by elevated blood glucose concentrations. There are three criteria for diagnosing DM: (a) symptoms of diabetes and plasma glucose concentrations greater than 200 mg/dL (11.1 mmol/L) at any time, (b) fasting plasma glucose concentrations greater than 126 mg/dL (7 mmol/L), or (c) plasma glucose levels two hours postglucose load greater than 200 mg/dL.

Type I Diabetes Mellitus

Type I DM is a T-lymphocyte–mediated autoimmune disease that eventually results in the destruction of the islets of Langerhans of the pancreas. Although there appears to be a genetic element to the etiology of type I DM, the mechanism is uncertain. It predominantly affects Caucasians and tends to occur in patients <20 years of age. Male and female distribution is approximately equal.

Type II Diabetes Mellitus

Type II DM is associated with insulin resistance as well as decreased insulin levels. Thirty to ninety percent of cases have a genetic element. This is supported by the fact that it is very prevalent in certain ethnic groups. Prolonged high glucose levels result in a decrease in hepatic glucose production and increased levels of insulin. Eventually, the increased insulin levels cause a depletion of beta cells. There is also a downregulation of GLUT transporters in peripheral tissue. All of this results in increased plasma glucose levels.

Complications

Most complications relate to blood vessel damage. Some are due to accelerated atherosclerosis and are often termed macrovascular effects. They include effects on the coronary, carotid, and femoral arteries. Accelerated atherosclerosis due to diabetes is manifested by endothelial injury, increased platelet adhesion, and aggregation as well as direct effects of hyperglycemia on plaque formation. Microvascular effects of diabetes result from the thickening of the capillary basement membranes with resulting changes in permeability and a loss of structural integrity. They are manifested in particular by retinopathy, nephropathy, and neuropathy.

Diabetic Ketoacidosis

Diabetic ketoacidosis can be fatal if it is not treated in a timely fashion. This is due to absolute insulin deficiency and glucagon excess leading to increased gluconeogenesis, glycogenolysis, and ketosis. This most often occurs in those with type 1 diabetes. Occasionally, patients with type 2 diabetes may also develop ketoacidosis but it is rare. Patients classically present with polyuria, polydipsia, abdominal pain, nausea, vomiting, and shortness of breath. In severe cases, lethargy and coma develop. On exam, patients often have signs of volume depletion (in severe cases, hypotension), tachycardia, Kussmaul respiration, and a fruity breath. Laboratory testing shows elevated blood glucose more than 250 mg/dL, positive ketones, and metabolic acidosis along with electrolytes disturbance. Arterial pH is often less than 7.3 and in severe cases can be less than 7.

There is often a precipitating cause, which can be infection such as pneumonia, UTI, and URI or missing an insulin dose in those with a diagnosis of type 1 diabetes, myocardial infarction, stroke, or any other concurrent illness. The treatment should focus on volume replacement, insulin treatment, potassium replacement, and supportive therapy. Fluid replacement with NS is used first; 1 to 2 L of normal saline should be given as a bolus during the first 1 to 2 hours of treatment in those without cardiac history and making urine. IV fluids should then be changed to 0.45% saline given at 150 to 300 mL/h. When BG decreases to less than 250 mg/dL, D5 should be added to the 0.45% saline to keep BG between 200 and 250 mg/dL until the anion gap closes. For insulin therapy, 5 to 10 units of insulin can be given as a bolus initially. Afterward, it can be given at 0.1 unit/kg/h. BG should be monitored on an hourly basis. The target BG decrease should be 50 to 75 mg/dL/h. The drip rate can be titrated up or down depending on BG level and rapidity of BG changes. A well-validated protocol often works well. These patients often have an absolute potassium deficiency. It should be replaced as long as the potassium level is below 5 mg/dL and the patient is making urine. Electrolytes should be monitored every 4 hours initially and then daily. Patients generally improve within the first 24 hours with appropriate treatment. Once the patient begins to eat, insulin should be switched to SQ, and there should be a 2- to 3-hour overlap between IV insulin and long-acting insulin before discontinuing IV insulin to avoid recurrence of DKA. Meal time short-acting insulin needs to be started as well. The underlying causative factor should be actively sought and treated accordingly. Patients should be educated regarding self-management of diabetes and appropriate "sick" day insulin dosing to avoid future episodes of DKA.

Hyperglycemic Hyperosmolar State

Hyperglycemic hyperosmolar state (HHS) is a severe condition with a very high mortality rate. This occurs often in those with type 2 diabetes as a result of relative insulin deficiency leading to increased gluconeogenesis and glycogenolysis. Different from DKA, ketosis is often absent. Marked dehydration is a key feature in HHS due to osmotic diuresis and inadequate oral intake. A concurrent illness such as MI, stroke, and infection is often the precipitating cause. Patients usually present with a history of decreased oral intake, confusion, and coma. On exam, tachycardia, hypotension, and altered mentation are commonly seen. Laboratory test shows severe hyperglycemia, generally between 600 and 1,200 mg/dL; hyperosmolarity; and renal insufficiency. In contrast to DKA, acidosis and ketones are classically absent. Treatment is similar to DKA but with emphasis on more aggressive fluid replacement given the fluid deficit is often 9 to 10 L compared to 3 to 5 L in DKA. Initially, 1 to 3 L of fluid should be given over 2 to 3 hours. Care should be taken to avoid too rapid correction of hyperosmolar state leading to worsening of neurologic function. Sodium levels can be corrected with hypotonic fluid. To correct a free water deficit, 0.45% saline should be used when the patient is hemodynamically stable. Insulin therapy is important as well, and the dose is generally higher than that given in DKA. Patients often have a larger deficit in potassium, and careful replacement is essential to avoid arrhythmia. One important issue in HHS is the timely correction of the underlying etiology precipitating this condition as it is often an important factor in the mortality related to this condition.

Hypoglycemia

Hypoglycemia can be fatal or may lead to seizure and other severe neurologic sequelae. It is most often due to excessive exogenous insulin in the hospital setting. Patients present with palpitations, shakiness, sweating, hunger, anxiety, fatigue, cognitive impairment, confusion, or coma. On exam, pallor, diaphoresis, and tachycardia are seen. The treatment for mild hypoglycemia is to provide glucose containing fluid, food, or glucose tablets. About 15 g of carbohydrate will generally raise BG about 30 to 50 mg/dL. In those unable to eat, 25 g of glucose in the form of D50 can be given by a bolus infusion followed by IV infusion of D5 or D10. Glucagon injection can be given when there is no IV access or patient is not alert enough to eat. Once BG improves and patient becomes alert, a proper meal should be consumed.

Multiple Endocrine Neoplasia Syndromes

MEN syndromes can be classified into type 1, type 2a, and type 2b (Table 16.1). It is a group of autosomal dominant diseases affecting susceptible families with variable penetrance. MEN1 typically presents with early onset primary hyperparathyroidism, pancreatic neuroendocrine tumors, and pituitary adenoma. The cardinal feature of primary hyperparathyroidism is multigland neoplasia. The diagnosis of MEN1 is suggested by early onset of disease, multigland disease, and frequent recurrence of primary hyperparathyroidism. Pancreatic neuroendocrine tumors are the second most common manifestation of MEN1 and tend to occur concurrently with primary hyperparathyroidism. They are a major cause of morbidity as more than one-third display malignant features including hepatic metastasis (16,17). Gastrinomas account for more than half of all pancreatic neuroendocrine tumors and are often multiple, making surgical cure impossible. The currently suggested treatment is medical therapy with proton pump inhibitors (18). Among the pituitary tumors, prolactinoma is the most common type of adenoma. The MEN1 gene encodes a tumor suppressor protein menin. Mutation in MEN1 gene leads to uncontrolled cell growth in selective tissues in patients with MEN1 syndrome (19). The MEN1 gene has been mapped to chromosome 11.

TABLE 16.1 MEN SYNDROMES

Syndrome	Neoplasias
MEN1	Hyperparathyroidism (90%–95%)
	Pancreatic neuroendocrine tumors (75%–80%)
	Pituitary adenoma (65%)
MEN2a	Medullary thyroid carcinoma (97%–100%)
	Hyperparathyroidism (50%–60%)
	Pheochromocytoma (10%–35%)
MEN2b	Medullary thyroid carcinoma (90%)
	Pheochromocytoma (40%–50%)
	Mucosal neuroma (100%)
	Marfanoid habitus

The classic MEN2a patients have medullary thyroid cancer, pheochromocytoma, and primary hyperparathyroidism. The genetic abnormality responsible for MEN2a is a mutation of RET proto-oncogene located on chromosome 10. Medullary thyroid cancer occurs as a result of c cell hyperplasia and develops universally in MEN2a. The treatment of medullary thyroid cancer is total thyroidectomy. There is a direct correlation between MEN2a mutation and development of medullary thyroid cancer. Prophylactic thyroidectomy should be performed as early as possible on those carriers of the mutation to optimize outcomes. Pheochromocytoma occurs in more than 50% of the patients and is often bilateral and multicentric and almost always found in the adrenal gland. It typically occurs later than medullary thyroid cancer. Primary hyperparathyroidism occurs less often than in patients with MEN1, occurring in about 15% to 20% of patients.

MEN2b patients are affected by medullary thyroid cancer, pheochromocytoma, mucosal neuromas, and marfanoid habitus. The mucosal neuromas and marfanoid habitus are the most distinct features and are recognizable in childhood. Neuromas are present on the tip of the tongue, under the eyelids, and throughout the gastrointestinal tract (17). The MEN2b mutation involves RET proto-oncogene too, but the specific point mutation is distinct from MEN2a resulting more aggressive types of MTC with metastasis developing in children sometimes prior to 1 year of age. The incidence and clinical course of pheochromocytoma are similar to that in MEN2a.

Other malignant and nonmalignant tumors are also found at higher frequency in patients with MENs such as subcutaneous or visceral lipomas and cutaneous leiomyomas, angiofibromas, and collagenomas (16). For patients with MENs, a strong family history is often present. Genetic testing is helpful in diagnosis of MENs. It is especially important for those with MEN2a or MEN2b as identification of the mutation will alter management and mandate long-term follow-up. It should be routinely performed on family members to identify carriers of the mutated RET proto-oncogene. The genetic testing in MEN1 patients serves the purpose of guiding long-term follow-up (16). It should be routinely performed on family members to identify carriers of the mutated RET proto-oncogene.

HORMONE-SECRETING TUMORS

Catecholamine-Secreting Tumors

Catecholamine-secreting tumors are seen in 2 to 8/million population. They may secrete epinephrine, norepinephrine, or dopamine. They are often divided into what are termed pheochromocytoma, a tumor of the adrenal medulla, and paraganglioma, which can be associated with other sites of chromaffin cell origin, including the para-aortic parasympathetic nerves, cervical and mediastinal parasympathetics, the organ of Zuckerkandl (at the origin of the inferior mesenteric artery), and the wall of the bladder. These tumors are equally distributed between the sexes, and 10% to 20% have a familial component. They usually occur in the third to fifth decade of life. When they occur in children, they are almost always familial. Pheochromocytomas are discussed elsewhere in this chapter. The focus here is on paragangliomas, particularly, of the head and neck.

Head and neck paragangliomas are less likely to be secreting tumors than paragangliomas elsewhere (about 5%). About 15% to 20% are genetic and tend to occur at an earlier age. Mutations in succinate dehydrogenase, a tumor suppressor gene, are most commonly associated with familial paraganglioma. (20) Mutations involving the C and D subunit are more commonly associated with head and neck paraganglioma. Inheritance is autosomal dominant. Up to 50% of familial paraganglioma may be multifocal. Mutations associated with the B subunit are more likely to be malignant but are typically associated more with paraganglioma of the abdomen and pelvis. Paraganglioma of the head and neck rarely is associated with von Hippel-Lindau disease.

Symptoms are often determined by the site of origin, many of them being found incidentally. Paraganglioma of the jugular or tympanic plexus may present with hearing loss or a mass in the middle ear. Vagal paraganglioma may present with vocal cord paralysis. Carotid body paraganglioma may present with a mass in the neck. Even though only a small percentage of these are secreting tumors, because of the risk of multifocality including the possible presence of a pheochromocytoma, screening for fractionated plasma free metanephrines or 24-hour urine for metanephrines and other catecholamine products may be indicated.

Diagnosis of head and neck paraganglioma is made by MRI with gadolinium enhancement. Flow voids are prominent because of the vascular nature of the tumor. Angiogram may be a useful adjunct, both to visualize the tumor and to embolize large vascular tumors.

TABLE 16.2 ENDOCRINE DISORDER DIAGNOSIS

Endocrine Diagnosis	Symptoms	Tests
Pituitary adenoma	Related to hormone excess or deficiency, mass effects	MRI of pituitary glands, stimulation or suppression tests for hormone abnormality
DI	Polyuria, polydipsia	Urine specific gravity, plasma osmolarity, water deprivation test
Syndrome of inappropriate secretion of ADH	Delirium, fatigue	Serum electrolytes, urine osmolarity, urine sodium level
Hypercalcemia	Fatigue, anorexia, bone and joint pain, renal colic, hematuria, constipation, delusion	Serum calcium, phosphorus, albumin, PTH, alkaline phosphatase, sestamibi scan, 24-h urine calcium/creatinine
Hypocalcemia	Muscle irritability, tetany	Calcium, magnesium
Diabetes	Polyuria, polydipsia	HbA1c, fasting, or 2-h oral glucose tolerance test
Diabetic ketoacidosis	Confusion or coma, acetone breath	Electrolytes, ketone, blood gas
Hyperthyroidism	Increased metabolic rate	TSH, fT4
Hypothyroidism	Cold intolerance, fatigue, constipation, impaired mental functions, dry brittle hair	TSH, fT4
Carcinoid tumors	Diarrhea, flushing, wheezing, valvular disease	24-h urine 5-HIAA
Pheochromocytoma	Hypertension, "spells"	Plasma or 24-h urine metanephrines, CT or MRI or ^{131}MIBG

Definitive treatment is surgical, but in cases of multifocality, the decision for surgery and the timing of that surgery may be difficult because of the associated morbidity. Radiation therapy may control growth of the tumor for a period of time but is not a cure (21). Malignancy can only be determined by the presence of paraganglioma in lymph nodes by pathology.

Carcinoid Tumors

These tumors are often associated with the GI tract, although they can be associated with the lung and rarely other parts of the body. They are neuroendocrine tumors of enterochromaffin cell origin. They can produce a wide array of hormones including gastrin, gastrin-releasing peptide, ghrelin, calcitonin, pancreatic polypeptide, ACTH, CRH, and GHRH, as well as somatostatin, glucagon, and calcitonin gene–related peptide. The most commonly secreted is the glycoprotein chromogranin A. Incidence is 2.8 to 4.5 per 100,000 population. They are most often classified using the World Health Organization system as well-differentiated endocrine tumors, well-differentiated endocrine carcinoma, and poorly

TABLE 16.3 ENDOCRINE EMERGENCIES

Endocrine Diagnosis	Emergency	Complication
Pituitary adenoma	Pituitary apoplexy	Loss of vision
DI	Hypernatremia	Seizure or coma
Syndrome of inappropriate secretion of ADH	Hyponatremia with sodium <125 mEq/L	Seizure or coma
Hyperparathyroidism	Hypercalcemia > 13 mg/dL	Arrhythmias, renal failure, death
Hypoparathyroidism	Hypocalcemia <7 mg/dL	Laryngospasm, seizures
Diabetes	Diabetic ketoacidosis	Coma, death
Hyperthyroidism	Thyroid storm	Heart failure, delirium, death
Hypothyroidism	Myxedema coma	Coma, death

TABLE 16.4 PERIOPERATIVE CONSIDERATIONS

Catecholamine-producing tumors

Alpha-adrenergic blockade for 7–10 d prior to surgery
- Phenoxybenzamine 10 mg BID, increasing 10–20 mg every 2 to 3 d
  - Titrate to BP < 120/80 mm Hg with systolic >90 mm Hg

Beta-adrenergic blockade after meeting targets with alpha-adrenergic blockade
- Propranolol 10 mg every 6 h, titrating up for goal heart rate of 60–80 beats/min

Calcium channel blockers can be used as alternative or in conjunction with prior regimen
- Nicardipine

Intraoperative acute hypertension
- Nitroprusside 0.5–5 mg/kg/min then titrated or
- Phentolamine 1 mg test followed by 5 mg bolus 10–15 mg infusion
- Nicardipine 5 mg/h then titrate up for desired effect

Intraoperatively—avoid fentanyl, ketamine, morphine, atropine, halothane, and desflurane

Thyrotoxicosis

Preoperative goal—restore normal metabolism
- Antithyroid agents
- Propylthiouracil 150–200 mg every 8 h, then titrate to effect
- Methimazole 10–15 mg BID initially, then titrate

After normalization
- Saturated solution of potassium iodide 2–3 drops/d for 7–10 d
- Lugol solution 5–10 drops/d for 7–10 d

Propranolol used as an adjunct for residual adrenergic symptoms
- 20–60 mg every 6–8 h

DI

Post–pituitary surgery
- Desmopressin IV 0.5–2 mcg
- 6–24-h effect

Posttrauma
- Desmopressin 0.25–2.7 mU/kg/h
- Fluid replacement as appropriate

Prior to routine procedure
- Parenteral or nasal dose prior to surgery if NPO

differentiated endocrine carcinoma. Well-differentiated endocrine tumors are typically serotonin-secreting midgut tumors that are small, noninvasive, and have a low proliferative index. Well-differentiated endocrine carcinomas are characterized by serotonin-producing tumors with or without carcinoid syndrome, possibly bronchial carcinoid. They are larger and often present with metastases and have a higher proliferative index. Both well-differentiated tumors and carcinomas may be functioning or nonfunctioning. Poorly differentiated carcinomas (small cell tumors) are larger more invasive tumors with the highest proliferative index.

Carcinoid tumors of the foregut and midgut secrete serotonin and have elevated urine 5-hyrdroxyindoleacetic acid. Foregut tumors more often primarily secrete 5-hydroxytryptophan, a precursor to serotonin.

Carcinoid syndrome is characterized by flushing, diarrhea, right-sided heart failure, and sometimes bronchial constriction and increased urinary levels of 5-HIAA. It is associated with tumors of the small intestine and proximal colon and is a function of tumor mass and location of metastases. It is less often associated with bronchial carcinoid tumors.

HIGHLIGHTS

- The residue of Rathke's pouch separates the anterior and posterior lobes of the pituitary gland.
- Fifty percent of anterior pituitary cells are somatotrophs secreting GH.
- The pituitary lies outside the arachnoid space and the CSF containing compartment of the dura.
- GH effects are mediated by IGF1 and 2.
- Medical therapy for prolactinomas involves dopamine agonists bromocriptine and cabergoline.
- ACTH secretion is pulsatile with up to 40 pulses per day.
- LH, FSH, TSH, and bHCG all share a common a common alpha subunit but distinct beta subunits.
- TSH release follows a circadian rhythm with peak levels around 11 PM and 5 AM.
- ADH plays a critical role in water homeostasis and the osmolality of body fluids. It is characterized by high volume, hypotonic, dilute urine.

- PTH levels vary inversely with ionized calcium levels, and PTH response is greater for a given level of hypocalcemia if the rate of decrease in calcium is higher.
- Primary hyperparathyroidism is defined by the inappropriate hypersecretion of PTH.
- Vitamin D receptors in the duodenum and jejunum induce calcium channels in the gut with subsequent intestinal absorption of calcium.
- Insulin induces glycogen synthesis in the liver but does not increase glucose uptake by the liver. It does recruit GLUT transporters in muscle and adipose tissue, thus inducing glucose uptake in those tissues.
- Complications of diabetes are usually related to macrovascular disease associated with accelerated atherosclerosis or microvascular disease associated with thickening of capillary basement membranes.
- Mutations in the succinate dehydrogenase are commonly associated with familial paraganglioma.
- Hypothalamic DI can occur after surgery in the vicinity of the pituitary and hypothalamus.
- Thyroid function is positively regulated by TRH released by hypothalamus and TSH produced by pituitary gland. It is negatively regulated by thyroid hormones produced by thyroid gland.
- TSH and fT4 are most useful tests to evaluate thyroid dysfunction.
- Thyroid hormones bind to nuclear receptors to exert its function. Both T3 and T4 are produced by the thyroid gland, but T3 is the more biologically active thyroid hormone.
- Genetic testing in MEN2b patients is essential as it can identify carriers of the RET proto-oncogene mutation so that prophylactic treatment can be performed.
- Pheochromocytoma is rare but has high mortality if not recognized or treated appropriately. Adequate alpha-adrenergic receptor blockade along with fluid expansion is essential in reducing perioperative mortality.

17 Rheumatologic, Granulomatous, and Other Systemic Diseases Affecting the Head and Neck

Valentin D. Marian *Anurag Gandhi* *Shawn D. Newlands*

The otolaryngologist can play two important roles in the care of patients with systemic medical disorders first seen with head and neck symptoms. The first role is to diagnose these disorders based on clinical findings in the head and neck, through a high index of suspicion for these diseases. The second role is, in collaboration with a rheumatologist or infectious disease specialist, to manage head and neck manifestations of these diseases. This chapter covers an array of rheumatologic, granulomatous, and other systemic diseases that might, commonly or rarely, be seen for diagnosis or treatment by an otolaryngologist. The theme of this chapter is systemic diseases that can affect multiple head and neck sites. Amyloidosis and bony lesions are included in this chapter because they do not neatly fit into other anatomical or discipline-specific chapters in this text. Diseases that are limited to one head and neck site are discussed in the site-specific chapters of the text.

RHEUMATOLOGIC DISEASES

Rheumatologic diseases have patterns of organ involvement that not only overlap each other but overlap other diseases as well, which frequently makes specific diagnosis difficult. When first recognized as a distinct histopathologic characteristic for a collection of diseases, perivascular collagen deposition prompted the name *collagen vascular diseases*. However, the term "collagen vascular disease" is a misnomer, these diseases affect many different proteins in addition to the collagen, and they affect many structures in addition to vascular structures. Subsequently, the association of the collagen vascular diseases with immunologic reactions to body proteins prompted many to call these disorders *systemic autoimmune diseases*. This collection of diseases includes not only classical connective tissue diseases, such as systemic lupus erythematosus (SLE), Sjögren syndrome, and scleroderma, but also vasculitides and musculoskeletal autoimmune syndromes. In contrast with systemic autoimmune disease are the organ- or tissue-specific autoimmune diseases, such as type I diabetes mellitus, Hashimoto thyroiditis, myasthenia gravis, and multiple sclerosis. In addition, many pure connective tissue diseases (such as scurvy, Ehlers-Danlos, and Marfan syndrome) are not autoimmune in nature.

The exact cause of systemic autoimmune diseases remains obscure. The prevailing histopathologic feature of these diseases is a varying amount of connective tissue and blood vessel inflammation with abundant fibrinoid deposits (Fig. 17.1). The tissue distribution of the inflammatory response and the pattern of organ involvement differentiate one systemic autoimmune disease from another. Specific autoantibodies are associated with some of these entities (Table 17.1), although many of these autoantibodies are present in several autoimmune diseases and other conditions. Thus, clinical diagnosis is based on the constellation of symptoms, signs, laboratory tests, and histopathology. Diagnostic criteria have been developed for the majority of these conditions.

Systemic Lupus Erythematosus

SLE is a common systemic autoimmune disease. According to a recent report from the National Arthritis Data Working Group, approximately 250,000 Americans have systemic lupus (1), making the incidence of the disease approximately 1 in 1,400, with nine women affected for every man. The course of SLE is highly variable, affecting primarily women of childbearing age. The disease also is three times more common in African-Americans than in white Americans. Protean systemic manifestations include arthritis, constitutional symptoms, photosensitive skin eruptions, serositis (pleurisy, pericarditis), nephritis, leukopenia, anemia, hypercoagulability, and central nervous system (CNS) involvement (most commonly cognitive dysfunction and intractable headaches). The classification

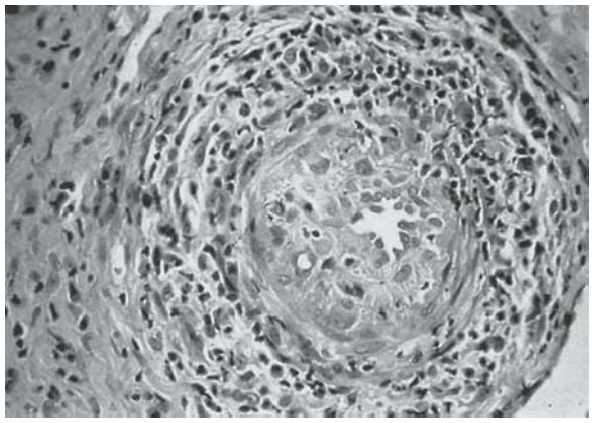

Figure 17.1 Necrotizing and fibrinoid necrosis is seen in many connective tissue diseases. This biopsy from a patient with PAN shows an infiltration of eosinophils and polymorphonuclear leukocytes with medial necrosis and intimal proliferation.

criteria for SLE are outlined in Table 17.2 (2). Infectious complications related to active SLE and immunosuppressive treatment are now the most common cause of death in early active SLE, and accelerated arteriosclerosis is the main cause of late mortality (3), although the survival rate with this disease is now about 90% at 10 years and 70% at 20 years; this rate has been improved over time (4).

Head and Neck Manifestations

The head and neck manifestations of SLE are dominated by skin and mucosal lesions. In 35% to 40% of patients, a malar or "butterfly" rash is the first sign of the disease and is commonly precipitated by sunlight exposure (**Fig. 17.2**). Thirty-seven percent of patients with SLE have photosensitive skin, and sunlight exposure can trigger not only the skin rash but also systemic disease exacerbations. Additional manifestations of SLE are seen in many forms. Associated oral lesions are in general of three types: erythematous, discoid, and ulcerative. Discoid lesions are superficial; have a well-defined elevated border; may be painful; and show pronounced hyperemia, edema, and white dots with a tendency toward bleeding. Localized telangiectasia may produce a red halo effect around the affected mucosa, and secondary moniliasis and xerostomia also are common. Ulcerative lesions are usually shallow, often occur in crops, most commonly are found on the hard palate, but the buccal mucosa or nasopharynx is affected in one-third of patients. Involvement of larynx and nasal mucosa has been described. Mucosal ulceration is painful, may persist or be cyclical, and tends to occur with disease flare. Erythematous lesions are the most common; they are usually painless, red, flat, and have ill-defined borders. Histologically, mucosal lesions in SLE demonstrate orthokeratosis and parakeratosis alternating with areas of epithelial atrophy. Keratotic plugging, acanthosis, and pseudoepitheliomatous hyperplasia are common findings. Superficial, perivascular, and deep lymphocytic infiltration can be seen throughout the mucosa, and skin lesions may show only inflammation or, by immunofluorescence (IF), immune deposits at the dermal–epidermal junction.

Numerous other head and neck problems may be associated with SLE. In 3% to 5% of well-established cases,

TABLE 17.1 AUTOANTIBODY RELATIONS IN RHEUMATOLOGIC DISEASES

Disease	Autoantibody
SLE	ANA (95%–100%), Anti-ds DNA (50%), Anti-Sm (25%), Anti-ss DNA (80%), Anti-La/SSB (20%), Anti-Ro/SSA (50%)
RA	ANA (50%), RF (90% in severe disease)
Primary Sjögren syndrome	ANA (65%), RF (85%), Anti-Ro/SSA (75%), Anti-La/SSB (% of those with Anti-Ro/SSA)
SSc	ANA (80%), Anti-Scl-70 (30%), Anti-centromere (30%)
Polymyositis/ dermatomyositis	ANA (80%), Anti-Jo-1 (20%)
MCTD	ANA (100%), Anti-U1-RNP (100%), RF (55%)
Granulomatosis with polyangiitis	c-ANCA (90%)

TABLE 17.2 CLASSIFICATION CRITERIA FOR SYSTEMIC LUPUS ERYTHEMATOSUS (2)

Clinical Criteria

1. Acute or subacute cutaneous lupus lesions
2. Chronic cutaneous lupus lesions
3. Oral or nasal ulcers
4. Non-scarring alopecia
5. Synovitis involving 2 or more joints, characterized OR tenderness in 2 or more joints and at least 30 minutes of morning stiffness
6. Serositis
7. Renal disease (proteinuria >500 mg protein/24 hours OR red blood cell casts)
8. Neurologic (seizures, psychosis, mononeuritis multiplex, myelitis, peripheral or cranial neuropathy, acute confusional state)
9. Hemolytic anemia
10. Leukopenia (<4,000/mm^3 at least once) or lymphopenia (<1,000/mm^3 at least once)
11. Thrombocytopenia (<100,000/mm^3) at least once

Immunologic Criteria

1. Elevated ANA level
2. Elevated Anti-dsDNA antibody level
3. Anti-Sm antibody positivity
4. Antiphospholipid antibody positivity
5. Low complement
6. Direct Coombs' test (in the absence of hemolytic anemia)

The diagnosis of SLE requires satisfaction of four of the clinical and immunologic criteria, including at least one clinical criterion and one immunologic criterion, or if biopsy-proven nephritis is compatible with SLE in the presence of ANAs or anti-dsDNA antibodies. All clinical criteria count only if not other cause is apparent.

Figure 17.2 Facial rash in the butterfly distribution typical of SLE.

recurrent nasal mucosa ulcerations occasionally lead to nasal septal perforation. Inflammatory changes of the larynx and trachea have been described, including true vocal fold thickening or paralysis, cricoarytenoid arthritis, hoarseness due to recurrent laryngeal nerve paralysis, edema with airway obstruction due to necrotizing vasculitis, and subglottic stenosis. Up to 25% of SLE patients report dysphagia. In 10% of SLE patients, acute enlargement of the parotid gland occurs and may be unilateral, tender, and confused with acute parotitis. Additionally, xerostomia may become a chronic problem. Sicca complex alone or in association with secondary Sjögren syndrome is a common finding in SLE patients.

Neuropathy also is a major characteristic of SLE, and in 15% of patients, the cranial nerves are affected. The neuropathy may involve the motor supply to the extraocular muscles, the sensory divisions of the trigeminal nerve, the motor divisions of the facial nerve, the vestibular portion of the vestibulocochlear nerve, or the optic nerve. Sudden hearing loss also has been described with SLE, although a definitive link has not been established. Such hearing loss may be due to thrombosis or vasculitis, although temporal bone studies have been inconclusive. A nonspecific lymphadenopathy associated with SLE in some cases appears to be related to skin or mucosal lesions.

Discoid lupus erythematosus is a subtype of SLE in which cutaneous lesions result in significant scarring but with no visceral involvement. These lesions are well-demarcated, erythematous, edematous papules that depigment and scar on resolution. The face is involved in 85% of cases, the scalp in 60%, and the ear in 44%. Associated leukoplakia of the tongue and oral mucosa may occur.

Treatment

Management of this severe and complex disease is complicated and specialized, and as such, requires a rheumatologist (5). Because many SLE patients are highly photosensitive, avoidance of sun exposure and liberal use of sunscreens are recommended. The general treatment of SLE includes nonsteroidal anti-inflammatory drugs, topical and low-dose systemic steroids, and antimalarials (especially hydroxychloroquine). Low-dose methotrexate may be an alternative to systemic steroids. The use of high-dose systemic steroids and immunosuppressive agents, such as mycophenolate mofetil, azathioprine, and cyclophosphamide, is restricted to cases with visceral involvement that might lead to organ (heart, kidney, CNS) damage. Newly developed biologic agents, such as rituximab—a chimeric monoclonal antibody that targets B-lymphocyte surface marker CD20, show promising results for the treatment of lupus. A fully human monoclonal antibody, belimumab, targeted against soluble B lymphocyte stimulator (Blys) has been recently approved by FDA for the treatment of patients with active, autoantibody-positive systemic lupus erythematosus who are receiving standard therapy. This is the first biologic therapy approved for the treatment of lupus and followed a successful clinical trial where belimumab plus standard therapy was shown to reduced SLE disease activity and severe flares (6). Symptomatic treatment of the head and neck manifestations of SLE, as with all systemic autoimmune diseases, is required when the systemic steroids become ineffective. Many patients complain about the loss of salivary flow and the development of oral and pharyngeal lesions, and treatments are varied. Saliva substitutes often prove helpful for this complaint. Steroid-based topical solutions for the treatment of mouth ulcers are effective if administered appropriately. Ointments and creams designed for intraoral use are not effective, but mouthwashes are useful when administered frequently and held in contact with the diseased tissues for several minutes. One such preparation is Klacks solution, which consists of tetracycline, cortisone, diphenhydramine, and nystatin. Postprandial cleansing using mouthwashes with stock hydrogen peroxide solution diluted with equal parts of warm tap water also may help oral lesions. In selected cases, for patients with resistant mucosal disease dapsone and thalidomide can be helpful; however, the side effect profile limits their use (7).

Rheumatoid Arthritis

Rheumatoid arthritis (RA) is a chronic systemic inflammatory disease of unknown cause that primarily presents with inflammation of synovial tissue. Symmetrical involvement of the peripheral joints is the dominant clinical feature. The course of the disease is variable, usually progressive, and may affect nonarticular tissues. RA occurs in 1% of the population, affecting women two to three times more often than men. Although it may occur at any age, and a distinct juvenile variety exists, it is more common in the fourth to fifth decade. The onset of RA may be acute, but more frequently

TABLE 17.3 THE 2010 AMERICAN COLLEGE OF RHEUMATOLOGY/ EUROPEAN LEAGUE AGAINST RHEUMATISM CLASSIFICATION CRITERIA FOR RHEUMATOID ARTHRITIS (8)

Target Population

(1) Patients who have at least 1 joint with definite clinical synovitis
(2) Patients with the synovitis not better explained by another disease

Classification criteria for RA (score-based algorithm: add score of categories A–D; a score of 6/10 is needed for classification of a patient as having definite RA)

Joint involvement	1 large joint	0
	2–10 large joints	1
	1–3 small joints	2
	4–10 small joints	3
	>10 joints (at least 1 small joint)	5
Serology	Negative RF and negative ACPA	0
	Low-positive RF or low-positive ACPA (anticitrullinated peptide antibodies)	2
	High-positive RF or high-positive ACPA	3
Acute-phase reactants	Normal CRP and normal ESR	0
	Abnormal CRP or abnormal ESR	1
Duration of symptoms	<6 wk	0
	≥6 wk	1

it is insidious, with progressive joint involvement. Morning stiffness lasting more than 30 minutes and stiffness after prolonged inactivity are common symptoms. Tenderness and inflammation in an inactive joint are physical findings specific to RA, and subcutaneous rheumatoid nodules aid in the diagnosis. Nonarticular manifestations include visceral nodules, vasculitis, pleural or pericardial effusions, and Sjögren syndrome. The classification criteria for RA are found in Table 17.3 (8).

Head and Neck Manifestations

Articular involvement predominates in the diverse head and neck manifestations of RA, affecting the ossicles, temporomandibular joints, cricoarytenoid joints, and the cervical spine. Temporomandibular joint dysfunction may be prominent; causing many patients with RA to have temporomandibular joint complaints including pain or tenderness at the joint or in the masseter or temporalis muscles, crepitus, limited mobility, or deviation, and radiographic evidence of joint erosion is often present. Temporomandibular joint dysfunction in patients with RA may be severe and cause contractures of the muscles of mastication, producing an anterior open-bite deformity (9).

RA is the most frequent cause of arthritis in the cricoarytenoid joint. Histologic abnormalities of the cricoarytenoid joints are present in 86% of patients with RA. Clinically, however, only 30% of the patients with RA are hoarse. Cricoarytenoid arthritis may occur with dyspnea on exertion, anterior neck or ear pain, fullness in the throat, dysphagia, and aspiration. Hoarseness in RA is usually the result of cricoarytenoid joint involvement but may be caused by rheumatoid nodules within the cords and ischemic recurrent nerve paresis or paralysis (10). The sudden onset of stridor and dyspnea in a patient with RA is an emergency requiring systemic steroids and possibly a tracheostomy. The oral cavity is not usually involved with abnormalities related to RA unless associated Sjögren syndrome is present or medication side effect develops. In an uncommon variant of rheumatoid vasculitis, oral ulcers similar to those seen in polyarteritis nodosa (PAN) are found.

The middle ear may be involved in severe cases of RA if synovitis develops in the ossicular joints, but this occurrence rarely results in a conductive hearing loss, except during an acute RA flare. Stiffness in the incudomalleolar and incudostapedial joints does not impair sound conduction but does result in stiffness abnormalities detected on tympanometric testing. Autoimmune inner ear disease also has been related to RA, but no definitive mechanism has been proven (11).

Long-standing active RA may lead to cervical spine disease. Recurrent tenosynovitis involving the transverse ligament of atlas results in laxity and/or odontoid process erosion, in which case the ring of C1 can move forward in flexion causing cord compression. Any clinician should be aware about this entity and maintain a high index of suspicion when symptoms such as neck pain, stiffness, or radicular pain are present. Neck manipulation during endoscopic procedures or endotracheal intubation might precipitate atlantoaxial subluxation with subsequent cord compression. Physical examination may reveal abnormal protrusion of the axial arch on the posterior pharyngeal wall, loss of occipitocervical lordosis, and resistance to passive neck motion. Radiographic studies are necessary for the diagnosis.

Treatment

The treatment goal is to effectively control the synovitis and prevent the joint damage. The symptomatic relief

can be achieved using nonsteroidal and/or steroidal anti-inflammatory drugs. Disease-modifying agents should be initiated within the first 3 to 6 months of disease onset. Methotrexate is the most commonly used disease-modifying antirheumatic drug (DMARD) and gastrointestinal mucositis, including mucosal ulcerations and severe pharyngitis, occasionally complicates therapy. Methotrexate may be used alone or in combination with other conventional or biologic DMARDs. Sulfasalazine, hydroxychloroquine, and leflunomide are commonly used conventional DMARDs. If RA cannot be controlled with one or combination of conventional therapy, biologic DMARDs such as tumor necrosis factor inhibitors should be used, alone or in combination with methotrexate. Additional treatment goals include maintaining joint function and prevention of joint deformities. The otolaryngologic manifestations may require therapies directed at the specific symptoms.

Sjögren Syndrome

Sjögren syndrome is a chronic disorder characterized by immune-mediated destruction of exocrine glands, which are predominantly, but not exclusively, the lacrimal and salivary glands. Sjögren syndrome is important to be understood as a slowly progressive, SYSTEMIC autoimmune disease that affects primarily the exocrine glands. Systemic involvement is common; eventually more than three-quarters will develop one or more extraglandular manifestation. Sjögren syndrome occurs in 1% of the general population and in 10% to 15% of patients with RA. A 9:1 female preponderance is noted, and onset occurs between ages 40 and 60 years. Sjögren syndrome occurs in primary and secondary forms. The primary form is a diagnosis of exclusion. The secondary form refers to the sicca complex accompanying any of the systemic autoimmune diseases. The secondary Sjögren syndrome is seen primarily with RA but is also commonly associated with SLE, scleroderma, and primary biliary sclerosis. In one-third of patients with primary Sjögren syndrome, the disorder is systemic with involvement of extraglandular sites (arthritis 70%, Raynaud phenomenon 40% to 50%, pulmonary involvement 25% to 30%). Sjögren syndrome is associated with an increased (33 to 44 times) risk of lymphoma. The greatest risk for degeneration is seen in patients with the primary form, constant parotid swelling, splenomegaly, and lymphadenopathy, low C4 complement level and type II mixed monoclonal cryoglobulinemia. The majority of lymphomas are of mucosal-associated lymphoid tissue type.

The common clinical manifestations of Sjögren syndrome include xerophthalmia with secondary keratoconjunctivitis and xerostomia, with or without salivary gland enlargement. These manifestations are called sicca complex or sicca syndrome. A salivary gland biopsy is the best single test for Sjögren syndrome (specificity 83%, sensitivity 81%). A minor salivary gland biopsy usually demonstrates heavy lymphocyte infiltration, although a parotid biopsy may be more sensitive and specific. Rheumatoid factor and antinuclear antibodies are high in most Sjögren syndrome patients. Antibodies directed toward Sjögren syndrome A (Ro/SS-A) and Sjögren syndrome B (La/SS-B) antigens are noted in 60% and 30% of patients, respectively. These antibody tests lack specificity because they are commonly found in patients with SLE, RA, and polymyositis. Anti-La Ab is more specific than anti-Ro Ab, but less sensitive. Finding anti-La alone is atypical and was found more common in primary biliary cirrhosis or autoimmune hepatitis (12). In many anti-Ro–positive Sjögren syndrome patients, SLE will later develop. The classification criteria for Sjögren syndrome are outlined in Table 17.4 (13).

Confusion often is found between the designations of Sjögren syndrome and Mikulicz disease. The latter is swelling of the salivary glands accompanying nonsystemic autoimmune diseases, such as hyperlipoproteinemia, malnutrition, diabetes, cirrhosis, tuberculosis, and sarcoidosis. In the recent years, Mikulicz syndrome has been increasingly recognized as part of the spectrum of IgG4-related disease and not confined to salivary glands. It is characterized

TABLE 17.4 CLASSIFICATION CRITERIA FOR SJÖGREN SYNDROME (13)

The classification of Sjögren Syndrome will be met in patients who have at least two of the following three objective features:

1. Positive serum anti-SSA/Ro and/or anti-SSB/La or positive rheumatoid factor and ANA titer ≥ 1:320
2. Labial salivary gland biopsy exhibiting focal lymphocytic sialadenitis with a focus score ≥ 1 focus/4 mm^2
3. Keratoconjunctivitis sicca with ocular staining score ≥ 3 (assuming that individual is not currently using daily eye drops for glaucoma and has not had corneal surgery or cosmetic eyelid surgery in the last 5 y)

Prior diagnosis of any of the following conditions would exclude participation in SS studies or therapeutic trials because of overlapping clinical features or interference with criteria tests: history of head and neck radiation treatment, hepatitis C infection, acquired immunodeficiency syndrome, sarcoidosis, myloidosis, graft versus host disease, IgG4-related disease.

by infiltration of IgG4-positive plasma cells in the salivary glands tissue, raised serum levels of IgG4 and fibrosis or sclerosis. Sjögren syndrome is not related to the divergent group of systemic diseases associated with Mikulicz disease.

The autoimmune diseases of the parotid gland have a unifying histologic pattern of an early lymphocytic infiltrate, followed by thinning and fragmenting of the connective tissue in the terminal or intercalated duct walls with destruction of the acini. The larger ducts are usually uninvolved unless a superimposed infection is present. A diffuse pattern of globular collections of contrast material is observed, originally called sialectasis. It was initially thought that dilatation of the acini and collection of the contrast material within them was noted. It is now known, however, that the weakened acini allow extravasation of contrast material, which forms extramural globular collections. The four progressive radiographic features of autoimmune parotid swelling are punctate, with spherical collections of 1 mm or less; globular, with collections of 1 to 2 mm; cavitary, with large irregular collections of uneven distribution; and destructive, with no recognizable branching. The latter two stages represent superimposed infection.

Head and Neck Manifestations

Exocrine gland pathology dominates the head and neck manifestations of Sjögren syndrome. About 80% of these patients complain of xerostomia, the most prominent symptom of the disease. These patients report difficulty chewing, dysphagia, dysgeusia, fissures of the tongue and lips, and an increased number of dental caries. Oral candidiasis and angular cheilitis are frequent complications of dry mouth. Additionally, diminished secretion of tears leads to keratoconjunctivitis sicca and eye complaints, including dryness, burning, itching, and foreign-body sensation. Loss of glandular secretions in the nasal passages causes crusting and secondary epistaxis in 50% of patients and hyposmia in 40%. Chronic sinusitis may result from inspissated secretions, and occlusion of the nasolacrimal ducts may occur. Other manifestations of primary Sjögren syndrome include sensorineural hearing loss and, in 30% of patients, a painless intermittent unilateral parotid swelling of unpredictable duration that is rarely associated with edema.

Treatment

Symptomatic treatment is the primary approach to patients with Sjögren syndrome because no treatment alters the course of the disease. Patients and their primary care physicians must be made aware of the deleterious effects of decongestants, antihistamines, diuretics, and specific drugs used for the treatment of cardiovascular and psychiatric problems, known to produce a dry mouth. In addition to increasing oral fluid intake, the use of saliva and tear substitutes, pilocarpine and cevimeline may be helpful, but nonsteroidal and steroidal anti-inflammatory medicines fail to improve salivary flow. Antifungal medicines are used to treat oral candidiasis, and close supervision by a dentist and preservative dental treatments are essential. A more recent study showed that human interferon alpha used for dry mouth in 497 subjects had a significant greater mean increase in unstimulated whole saliva flow, compared with placebo (14).

Systemic Sclerosis (Scleroderma)

Scleroderma, also called systemic sclerosis (SSc), is characterized by sclerotic skin changes and is often accompanied by a multisystem disease. Progressive fibrosis of involved organs is the pathologic hallmark of the disease. Scleroderma is usually divided into two main forms: localized scleroderma and SSc. This division has important prognostic implications and allows specific clinical approach. SSc is further divided into limited cutaneous disease (lcSSc) and diffuse cutaneous disease (dcSSc). LcSSc is characterized by skin thickening distal to the elbows and knee, severe Raynaud phenomenon preceding skin disease, anti-centromere antibodies, and later development of visceral involvement (gastrointestinal and lung, pulmonary artery hypertension [PAH] and interstitial lung disease). DcSSc is characterized by proximal skin thickening (thighs, trunk, and arms), significant visceral disease (lung, heart, kidney, and gastrointestinal), absence of anti-centromere antibodies, and a worse prognosis (15). The incidence is approximately 18 to 20 new cases per million per year and the disease has a 3:1 female-to-male preponderance, with 50 years as the median age of onset. Initial presentation includes Raynaud phenomenon, edema of the fingers and hands, and skin thickening. The American College of Rheumatology criteria for scleroderma include one major criterion (sclerodermatous skin changes proximal to the metacarpal–phalangeal joints) and two of three minor criteria: sclerodactyly, evidence of ischemia of the digits (digital pitting scars), and bibasilar pulmonary fibrosis on chest radiograph (16). These criteria were found to have 97% sensitivity and 98% specificity for the diagnosis of scleroderma. Visceral and often fatal manifestations are seen in the gastrointestinal tract, lung, heart, and kidneys. Arthralgias and muscle weakness are common musculoskeletal complaints, and Raynaud phenomenon is almost universal.

Head and Neck Manifestations

Eighty percent of patients with SSc have signs and symptoms involving the head and neck, and in 30% of those patients, the head and neck symptoms are part of the presenting complaints. In the skin, edema precedes epidermal atrophy and loss of appendages. Eventually, in 35% of these patients, facial tightness develops. A decreased ability to open the mouth is the initial complaint in 19% of patients, which is a secondary manifestation to skin changes. Additional skin manifestations include telangiectasias (19%), calcinosis (3%), and linear scleroderma, which usually affect the scalp and limbs. The typical facies associated with scleroderma consists of tight skin, thin lips, and vertical perioral furrows (Fig. 17.3). These skin changes represent a major aesthetic concern for patients (17). These

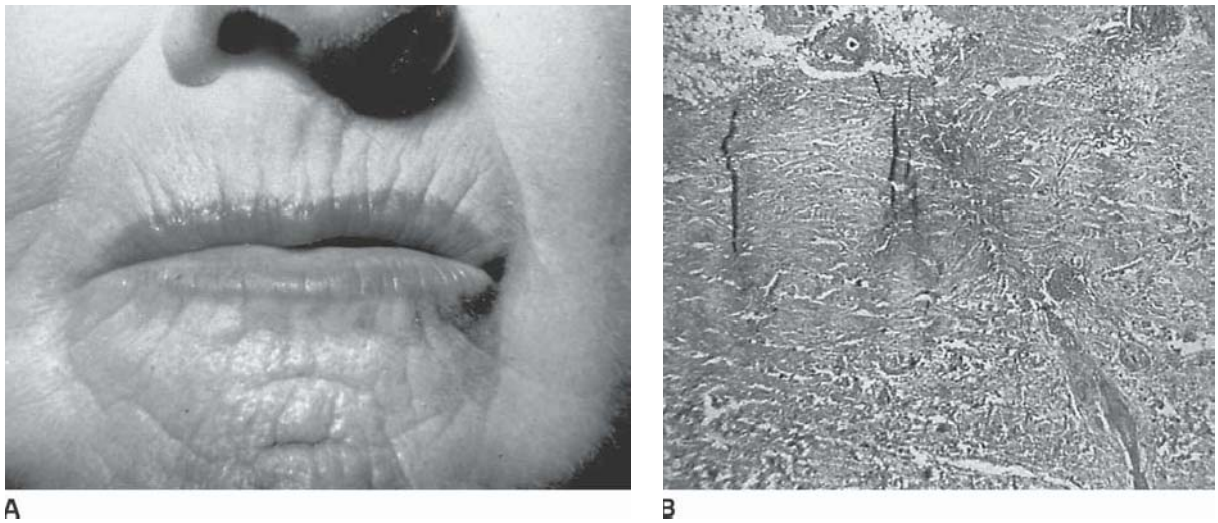

Figure 17.3 **A:** The typical facies of scleroderma: tight skin, thin lips, and vertical perioral furrows. These external facial features are secondary to inflammatory foci in the dermis and subcutaneous tissues. **B:** Infiltrations of lymphocytes, plasma cells, and histiocytes.

skin changes are secondary to the underlying dermal and subcutaneous inflammatory process. Dysphagia is the most common initial complaint. Esophageal problems occur in nearly all patients with this disease; abnormal radiographic findings are observed for the distal two-thirds of the esophagus in 80% of patients with SSc, and 50% of those patients are symptomatic. The dysphagia is due to involvement of esophageal innervation, smooth muscle (the distal two-thirds of esophagus, the portion composed of smooth muscle), esophageal stricture, or combination of all. Upper esophageal involvement does not usually occur unless there is an overlap with inflammatory myopathy, in which case even pharyngeal involvement can be seen, because of the striated muscle structure in the proximal esophagus. Decreased or absent peristalsis in the distal esophagus with mild to moderate dilation also is reported, and hiatal hernias are common.

Scleroderma often involves structures in the head and neck. Gingivitis and periodontal membrane thickening are common. Oral tissues demonstrate edema followed by atrophy and induration of mucosal and muscular tissues. About 25% of patients report xerostomia, xerophthalmia, or both (the sicca complex). A minor salivary gland biopsy will not demonstrate the lymphocytic infiltrate seen with Sjögren syndrome but will demonstrate fibrosis. Involvement of the larynx also occurs, and almost half of the patients with SSc complain of a voice change. The most common cause for laryngeal disease in scleroderma is chronic acid irritation from severe esophageal disease and incompetent lower esophageal sphincter. Raynaud phenomenon of the tongue, an unusual complication, may appear as mucosal blanching associated with dysarthria. Trigeminal neuralgia and facial nerve palsy are infrequent manifestations. Patients with SSc, particularly dcSSc, are at increased risk for development of carcinoma of the tongue (18).

Treatment

Randomized controlled trials in scleroderma have failed to reveal effective disease-modifying therapies (19). Thus, the treatment of SSc is largely symptomatic, although many rheumatologists will use immunosuppressive drugs in patients with active, progressive disease. Calcium channel blockers can be useful in Raynaud phenomenon but can aggravate gastroesophageal reflux. Proton-pump inhibitors are used with life-style modifications to treat gastroesophageal reflex in these patients, as in other patient groups. Dysphagia to solids can be helped by using liquids to clear the esophagus. Angiotensin-converting enzyme (ACE) inhibitors are used in the treatment of scleroderma renal crisis. Important advance has been made in the management of vascular disease of scleroderma, especially the PAH. FDA approved therapies for PAH in the United States include two endothelin-1 receptor blockers, two phosphodiesterase-5 inhibitors, and prostacyclin derivatives (20).

Inflammatory Muscle Disease (Polymyositis and Dermatomyositis)

The inflammatory myopathies are a group of disorders characterized by proximal muscle weakness and nonsuppurative inflammation of the skeletal muscle. Polymyositis, dermatomyositis, and inclusion body myositis are subsets of this group. The incidence of these disorders is estimated to be approximately five new cases annually per million, with a 2:1 female preponderance, and the age of onset is between 40 and 50 years, with a pediatric variant affecting children between the ages of 5 and 15 years. The diagnostic criteria for polymyositis and dermatomyositis are complex and subject to ongoing debate (21–23) (Table 17.5). The most common presentation is that of progressive proximal muscle weakness over a period of months, and fatigue is common.

TABLE 17.5 BOHAN AND PETER CRITERIA FOR THE DIAGNOSIS OF PM AND DM (22,23)

1. Proximal muscle weakness: usually symmetrical
2. Elevated serum muscle enzymes: CK, aldolase
3. Electromyographic abnormalities:
   (a) Common: myopathic potential—low amplitude, short duration, and polyphasic action potentials
   (b) Characteristic triad: (i) myopathic potentials; (ii) fibrillations, positive sharp waves, increased insertional activity; (iii) complex repetitive discharges
4. Muscle biopsy findings typical of PM or DM: necrosis, phagocytosis, regeneration, inflammation
5. Dermatologic features of DM, Gottron sign or papules, or heliotrope rash

Definite DM requires four criteria (including rash) and definite PM requires four criteria (without rash).
Probable disease comprises three criteria (including rash) for DM and three criteria (without rash) for PM.
Possible disease requires two criteria (including rash) for DM and two criteria (without rash) for PM.

The inflammatory myopathies may be isolated or associated with other abnormalities. Polymyositis and dermatomyositis may be associated with other systemic autoimmune disorders, including SSc, SLE, Sjögren syndrome, Churg-Strauss syndrome, and RA. In approximately 20% of patients, the myopathy is associated with a malignancy, particularly ovarian cancer, but non-Hodgkin lymphoma and carcinoma of the lung, prostate, breast, nasopharyngeal areas, and colon have also been implicated.

Head and Neck Manifestations

Head and neck manifestations of polymyositis reflect proximal muscle involvement. Half of the patients report weakness of the neck muscles, which is often manifested by a patient's inability to lift his or her head off a pillow. Difficulty in phonation and deglutition occurs because of diseased tongue muscles, and nasal regurgitation is common because of palatal and pharyngeal muscle involvement. Thirty percent of patients with these diseases have upper dysphagia secondary to the involvement of the upper esophagus, pharynx, superior constrictors or, most commonly in inclusion body myositis, the cricopharyngeus (24). Dysfunction of these muscle groups also results in aspiration and secondary pneumonia. Cutaneous photosensitivity is common in dermatomyositis. The heliotropic rash, seen in some (fewer than 50%) patients with dermatomyositis, is a purplish discoloration in the periorbital area, especially the upper eyelids.

Treatment

The treatment of inflammatory muscle disease starts with steroids to treat symptomatic patients. Methotrexate and azathioprine are commonly used as first steroid-sparing agents; they can be used alone or in combination for refractory myositis (25). Another important therapeutic approach with positive results in several perspective trials is intravenous immunoglobulin (Ig). Recently, rituximab has been used in a pilot study of dermatomyositis (26). Upper gastrointestinal symptoms related to esophageal dysfunction may require omeprazole, cisapride, or referral to a speech therapist. If untreated, the mortality rate from this disease is quite high. Physical therapy plays a role in reducing contractures and loss of function.

Relapsing Polychondritis

Relapsing polychondritis is characterized by episodic recurring inflammation of the cartilaginous structures and other tissues with a high concentration of glycosaminoglycans that are eventually replaced by granulation tissue and fibrosis. Diagnosis is based on chondritis at two of three sites (auricular, nasal, or laryngotracheal) or one of those three sites with two of the following symptoms: ocular inflammation, cochlear or vestibular damage (or both), or seronegative inflammatory arthritis (27). Biopsy of the lesion is not required for diagnosis. The incidence is about 3.5 cases per million.

Head and Neck Manifestations

Auricular chondritis and nonerosive arthritis are the most common presenting symptoms of relapsing polychondritis. Auricular chondritis is characterized by the sudden onset of erythema and pain, sparing the lobule, which lacks cartilage. Chondritis is the feature presentation in 33% of patients and will develop in 90% of those with the disease. Resolution can occur in 5 to 10 days with or without treatment. Conductive hearing loss may develop secondary to collapse of the external auditory canal or eustachian tube chondritis, causing serous otitis media, and 40% have cochlear or vestibular dysfunction, possibly due to vasculitis of the internal auditory artery. Aphthous ulcers are the most common dermatologic manifestations of this disease.

Chondritis of the nasal cartilages develops in 61% of patients and often does not coincide with auricular involvement (27). The nasal cartilage chondritis also has a sudden onset and resolves in several days with or without treatment. Overtime, and with repeated attacks, deformities result from the loss of cartilage. These deformities occur in the pinna, which become soft and flops over, and in the nasal bridge, which can cause a classic saddle deformity of the nose.

Laryngeal involvement is seen early with a nonproductive cough, which progresses to hoarseness and stridor. On physical examination, tenderness over the thyroid cartilage and the anterior trachea can be observed. Inflammation of the tracheobronchial tree damages the cartilaginous rings, which can cause a dynamic obstruction in inspiration. Stricture can form in subglottic space, increasing susceptibility to secondary infection. Of patients with relapsing polychondritis, 53% will have respiratory tract involvement during the course of their disease. Diagnostic endoscopy can be dangerous in these patients because of the risk of tracheal collapse. With extensive airway involvement, management is difficult, even with a tracheotomy. Indications for the need of a tracheotomy include severe edema of the glottic and subglottic regions of the larynx and laryngeal collapse.

Biopsy often reveals a lack of basophilic staining of the cartilage, perichondrial inflammation, with presence of mononuclear cell infiltrate at the fibrochondrial junction, and eventual cartilage destruction and replacement with fibrous tissue. The erythrocyte sedimentation rate (ESR) is often increased with active disease. Serologic evaluation often reveals a positive rheumatoid factor, antinuclear antibody, and anti-type II collagen antibody; however, the first two lack specificity and the last one is not routinely available. The clinical course ranges from mild disease to severe fulminating attacks. Mortality is generally related to respiratory involvement (i.e., laryngeal collapse) or cardiovascular disease (e.g., aneurysms or valvular insufficiency). The cause of relapsing polychondritis is unknown.

Treatment

Because of the relapsing nature of the disease, it is uncertain whether any therapy changes its course. In most cases, corticosteroids are the main form of treatment. Nonsteroidal anti-inflammatory medicines are used for arthritis. Colchicine may be used for auricular chondritis. The anti-leprosy sulfone drug dapsone also has helped in some cases, methotrexate is used when the arthritis component is an important feature, and azathioprine also has a place as a steroid-sparing agent. In the treatment of recalcitrant cases, treatment with infliximab may be successful (28,29). Surgery to correct the collapsed nasal cartilage and subglottic stenosis can be performed when disease is stable. Tracheal stenting is considered but experience is limited. Continuous positive airway pressure ventilation at night time might help to keep airway open while in the recumbent position.

Mixed Connective Tissue Disease

The term *mixed connective tissue disease* (MCTD) was coined in 1972 to describe a distinct entity with coexisting features of SLE, SSc, and myositis. This entity is characterized by high titers of anti-U1 RNP (1:1,600 or higher), a ribonucleoprotein antibody. The prevalence is unknown, and no consensus diagnostic criteria have been developed; the nature and existence of the disease as a unique entity is still debated. Eighty percent of patients are women, and onset usually occurs between the ages of 30 and 60 years, with death resulting primarily from pulmonary fibrosis and hypertension. The most acceptable criteria for diagnosis are those proposed by Alarcon-Segovia (30). Requirements for the diagnosis are anti-U1 RNP antibody positive at titer 1:1,600 or higher plus myositis or synovitis plus two of the following: edema of the hands, acrosclerosis, or Raynaud phenomenon.

Head and Neck Manifestations

Head and neck manifestations are a combination of the features seen in other systemic autoimmune disorders. Mucocutaneous changes include malar rash, discoid lupus, sclerodermatous skin thickening, oral mucosal ulceration, and nasal septal perforation. Sjögren syndrome also has been described in 50% of patients with MCTD, albeit sicca complex is usually less prominent than in those with anti-La antibodies. Esophageal dysfunction is present in most cases, resulting in abnormal peristalsis, heartburn, and dysphagia in 60%, 48%, and 38% of patients, respectively. One interesting clinical manifestation of MCTD that happens on a fairly frequent basis, in about 25% of cases, is trigeminal neuralgia. As with most other systemic autoimmune diseases, corticosteroid and immunosuppressive agents are the mainstays of treatment with the goal of managing the specific organ involvement or disease manifestations on a case-by-case basis.

Vasculitides

The vasculitides are a group of diseases characterized by a noninfectious necrotizing vasculitis and resultant ischemia. Considerable overlap in the clinical manifestations of these diseases makes it difficult to develop categories with strict criteria. A practical approach has been to classify them into groups by the size of vessels involved, the specific anatomic sites involved, clinical manifestations, and the presence or absence of anti-neutrophil cytoplasmic antibodies (ANCAs). Some of the more important categories are discussed herein.

Polyarteritis Nodosa

PAN has been considered the prototype of the vasculitides. This rare disease has an incidence of less than 1 in 100,000 per year. It affects males and females equally and is seen in all racial groups. Patients are usually in the fifth and sixth

decades of life at presentation. PAN is a non-ANCA vasculitis affecting predominantly medium-sized arteries and can be the result of hepatitis B infection. Tissues involved include the gastrointestinal tract, hepatobiliary system, kidneys (vascular nephropathy without glomerulonephritis), pancreas, skin, testicles, peripheral nerves, and skeletal muscles. Symptoms at presentation are primarily constitutional (fever, weight loss, and malaise) with peripheral neuropathy (mononeuritis multiplex).

Despite widespread arterial involvement, otolaryngologic manifestations are few, but sudden bilateral sensorineural hearing loss has been attributed to this disease. Vestibular disturbances also have been reported. The proposed mechanism of cochleovestibular damage is thromboembolic occlusion of the end arteries of the inner ear. Other head and neck manifestations include cranial nerve palsies, in which the seventh nerve is most commonly involved, and skin or mucosal lesions.

Churg-Strauss Syndrome

Churg-Strauss syndrome, also called allergic angiitis granulomatosis, is a disease characterized by the triad of systemic small-vessel vasculitis, asthma, and hypereosinophilia. Mean age at onset is 50 years, with a male preponderance and an incidence rate of approximately three per million. Three phases of this disorder exist. The prodromal phase consists of asthma, atopy, and allergic rhinitis; the latter symptom is present in 70% of cases. The second phase is marked by hypereosinophilia and eosinophilic tissue infiltration, leading to peripheral neuropathy or pulmonary infiltrates. Systemic necrotizing vasculitis constitutes the final phase, including renal, gastrointestinal, cardiac, and CNS involvement. Progression from asthma to vasculitis occurs over a period of 3 years to decades, and diagnosis of Churg-Strauss syndrome is suggested if four of six criteria (asthma; eosinophilia greater than 10%; neuropathy, mononeuritis multiplex, or polyneuritis; non-fixed pulmonary infiltrates; paranasal sinus abnormality; and extravascular eosinophilia) are present. Seventy percent of patients have nasal involvement, with polyps, resultant obstruction, rhinorrhea, secondary rhinosinusitis, and crusting. Asthma is nearly universal, and the ANCA serology (usually perinuclear or p-ANCA detected by IF and myeloperoxidase (MPO)-ANCA detected by enzyme-linked immunosorbent assay [ELISA]) is detected in 50% of the cases. Otologic manifestations of Churg-Strauss syndrome include sensorineural hearing loss and conductive hearing loss due to eosinophilic infiltration into the mastoid and middle ear with otorrhea. The middle ear and mastoid disease is reversed by steroid treatment (31). High-dose corticosteroids are the treatment of choice, but some patients with severe systemic involvement require cyclophosphamide. Deaths occur most commonly from cardiac and CNS involvement. Before the use of steroids, the mortality rate was 50% within 3 months of onset of the systemic vasculitis.

Granulomatosis with Polyangiitis (Wegener Granulomatosis)

Granulomatosis with polyangiitis (GPA) which is new nomenclature for the disease previously known as Wegener granulomatosis, is a rare (incidence of less than 1 in 100,000 per year) form of vasculitis characterized by the triad of upper and lower respiratory tract granulomas, vasculitis, and glomerulonephritis (Wegener triad), which could have been included in the granulomatous disease section of this chapter. No gender predilection is seen. Most patients are white and present in the fifth decade of life. The typical clinical features include bilateral pneumonitis (95% of patients), chronic sinusitis (90%), mucosal ulceration of nasopharynx (75%), and evidence of renal disease (80%). Nasal symptoms usually occur early in the disease and include crusting, epistaxis, and rhinorrhea. Erosion of the septal cartilage with saddle-nose deformity and nasal stenosis may occur after cartilage is destroyed by the vasculitis and granulomas. The sinusitis associated with GPA is difficult to treat. *Staphylococcus aureus* is often cultured from these patients.

The most common oral cavity findings of GPA include hyperplasia of the gingiva and gingivitis (strawberry gums). Edema and ulceration of the larynx are seen in 25% of patients. Significant subglottic stenosis develops in up to 23% of patients and is a poor prognostic sign. Salivary glands also may be involved.

Otologic problems develop in 20% to 25% of patients and include conductive hearing loss secondary to serous otitis media; suppurative otitis media, with or without granulation tissue in the middle ear; sensorineural hearing loss, often profound and bilateral; and pinna changes similar to those seen with polychondritis. Facial nerve palsies also have been documented, and is believed to be secondary to compression due to inflammation in the middle ear.

Diagnosis is based on clinical, pathologic, and laboratory findings. The hallmark pathologic lesion in GPA is necrotizing, granulomatous, small and medium vessel vasculitis with an inflammatory infiltrate. Often, upper-airway biopsies are nondiagnostic because the inflammatory infiltrate obscures the vasculitis, so that multiple upper-airway biopsies or lower-respiratory biopsies are required before histologic diagnosis is ultimately made. The discovery of cytoplasmic staining ANCA (c-ANCA) has revolutionized the diagnosis of GPA. The sensitivity of c-ANCA for GPA ranges from 65% to 96% for patients with an active, generalized disease, and the specificity is quite high, although this test may be positive in patients with microscopic polyangiitis (MPA) and Churg-Strauss Syndrome. ELISA provides target antigen-specific characterization of ANCA and enhances the specificity and sensitivity of IF. The c-ANCA pattern usually corresponds to detection of proteinase-3 ANCA (PR3-ANCA) by ELISA. Finding c-ANCA by IF in combination with PR3-ANCA by ELISA carries a sensitivities and specificities >95% for GPA

(32). Tissue diagnosis should be reserved for cases with high clinical suspicion but a negative PR3-ANCA or low clinical suspicion but positive PR3-ANCA. Classical clinical findings in conjunction with positive PR3-ANCA may be sufficient for diagnosis. The ESR varies with disease activity. Left untreated, generalized GPA is fatal within 2 years in 93% of all cases. However, symptomatic control of the disease is achieved in most patients with corticosteroids and low-dose daily cyclophosphamide (2 mg/kg/day). Some experts prefer regimens of monthly intravenous (IV) cyclophosphamide. Induction of remission with monthly IV cyclophosphamide was shown to be as effective as daily oral cyclophosphamide with fewer side effects (33). Azathioprine or methotrexate may be alternatives to cyclophosphamide and are used for the maintenance of remission or for patients with limited disease. Recently, the RAVE study has shown that rituximab therapy was not inferior to daily cyclophosphamide treatment for induction of remission in severe ANCA-associated vasculitis and may be a better option for recurrent disease. (34). Approximately 20% of patients, even with therapy, eventually succumb to the disease or to the therapy. Isolated sinus disease may be treated with low-dose steroids, topical nasal steroids, saline irrigations, or antibiotics when bacterial superinfection is suspected. Additionally, airway compromise may be alleviated with systemic steroids, although significant subglottic stenosis may require a tracheostomy.

Microscopic Polyangiitis

MPA is fairly recently described vasculitis, coined in 1994 by a group of experts during an international consensus conference. MPA essentially branched out from PAN as a small vessel disease. Vasculitis in the arterioles, capillaries, and venules, which involves primarily the lung and the kidney, are characteristic to MPA and absent in PAN. In addition, MPA patients commonly are ANCA positive unlike PAN. GPA, MPA, and Churg-Strauss syndrome comprise a category of small vessel vasculitis related to ANCA and are characterized by pulmonary and renal involvement. MPA and GPA have a similar clinical spectrum and are often hard to distinguish. Histopathologically, MPA is characterized by pauci-immune, necrotizing, small vessel vasculitis without evidence of granulomatous inflammation, in contrast with GPA where granulomatous vasculitis is the hallmark of disease. The prevalence is about 2 cases per 100,000 with white males being slightly more commonly affected than females; usual onset of disease is around 50 years.

The clinical presentation is similar with GPA. One of the most important differentiating factors between GPA and MPA is the severity and timing of upper respiratory tract involvement. MPA may affect the upper respiratory tract but is usually limited to a mild sinusitis, rhinitis, and mucosal lesions, and does not typically precede the disease onset. Fever, malaise, fatigue, myalgia, and weight loss is found in about 50%. Pulmonary involvement is common with infiltrates, hemoptysis, dyspnea, and cough. Renal disease in MPA is similar with GPA, but tends to present earlier in the disease. The most dreadful clinical presentation is with rapid progressive glomerulonephritis and kidney failure. Other organs and systems involvement are frequently found; patients with MPA might have gastrointestinal tract vasculitis, nervous system manifestations, more commonly mononeuritis multiplex (57%) but CNS involvement with seizure may be found in 11% of patients. Skin involvement (palpable purpura 40%, livedo reticularis, skin ulceration, and necrosis), ocular manifestation, myalgia, and arthralgia are part of the MPA clinical spectrum. Laboratory studies reveal elevated acute-phase reactants, anemia, and renal involvement (elevated BUN and creatinine, proteinuria, hematuria, and urinary casts). Eighty percent of the patients are ANCA positive and, in contrast with GPA, MPA typically exhibit a p-ANCA pattern on IF with MPO-ANCA reaction by ELISA. GPA typically has c-ANCA pattern on IF with PR3-ANCA by ELISA.

Treatment is identical for MPA as for GPA. The prognosis is relatively similar and the disease course is slightly different with a higher relapse rate for GPA (40%) and more frequent renal morbidity for MPA. In a retrospective study of 246 patients, 18% mortality was observed at 1 year and 76% survival at 5 years (35).

Giant Cell Arteritis/Polymyalgia Rheumatica

Giant cell (temporal) arteritis is characterized by focal granulomatous inflammation of arteries of medium and small size. Histologically, a panarteritis is seen with giant cell granuloma formation near the internal elastic lamina, which is often disrupted and concentric intimal hyperplasia. Giant cell arteritis is the most common of the vasculitides, and its incidence increases with age to approximately 20 cases per 100,000 persons aged 50 years and older in Northern European descent, 6 cases per 100,000 in Southern European and 1 to 2 cases per 100,000 in blacks and Hispanics. Giant cell arteritis is actually a general arteritis, of which temporal arteritis is only one local manifestation. Many rheumatologists believe this disease also encompasses polymyalgia rheumatica. Polymyalgia rheumatica is a clinical syndrome of muscular pain and morning stiffness in the proximal muscle groups without inflammatory joint or muscle disease. Patients with polymyalgia rheumatica have histologic changes in their arteries like those in temporal arteritis. In addition, polymyalgia rheumatica is seen in 50% of patients with classic giant cell arteritis. Systemic symptoms, such as low-grade fever, weight loss, and malaise, may precede localized symptoms in all manifestations of the disease. Polymyalgia rheumatica alone is usually self-limiting and responds well to low-dose prednisone therapy.

The symptoms of classic giant cell arteritis reflect involvement of the cranial blood supply by the vasculitis.

Headaches of variable character (throbbing, sharp, or dull) are the initial and the most common symptom in 47% of patients, and occur in as many as 90% of patients. Despite the name, the temporal artery is erythematous and tender in only 50% of patients with giant cell arteritis. The scalp, however, is often very tender. Other manifestations are presumably due to involvement of other arteries in the head and neck. Jaw claudication occurs in as many as 67% of these patients with prolonged talking or chewing, 25% have lingual claudication and cases of tongue infarction have been reported. Vertigo and hearing loss also have been reported. Involvement of the ascending pharyngeal artery can lead to dysphagia. Additionally, cranial nerve deficits, hemiparesis, vertebrobasilar insufficiency, and psychosis reflect intracranial disease. Blindness occurs in one-third of untreated patients and may be heralded by field defects, diplopia, or amaurosis fugax reported as fleeting visual blurring induced by exercises or sudden orthostatism. Sore throat and odynophagia may indicate ischemia of the pharynx and dry cough has been reported in the setting of vasculitis of the bronchial tree.

In giant cell arteritis, as with several of the vasculitides, the ESR is usually more than 50 mm/h. Although cases with normal or slightly elevated ESRs have been reported, those results usually lead the clinician away from the diagnosis. Confirmation of diagnosis of giant cell arteritis is accomplished with a biopsy of the temporal artery on the most symptomatic side. The false-negative results, however, range from 5% to 40% because of skip lesions and the frequently small foci of the disease in the artery. The American College of Rheumatology requires that three of five criteria (age older than 50 years at onset, new headache, temporal artery abnormality (tenderness or decreased pulsation), ESR more than 50 mm, and temporal artery biopsy showing vasculitis) be present to make the diagnosis. Thus, the role of temporal artery biopsy is to confirm the diagnosis when it is in doubt, although a negative biopsy does not rule out the disease. A positive biopsy is helpful if, after treatment, a question remains about the diagnosis. Because of the seriousness of the ophthalmologic consequences, treatment should not be delayed for the biopsy, as it is most useful within 24 hours of initiation of treatment (36).

Treatment for giant cell arteritis is corticosteroids. Using pulse IV corticosteroids (15 mg/kg/day) for the first 3 days allows a faster steroid taper and has a greater chance for a sustain remission (37). Normalization of the ESR or C-reactive protein and loss of symptoms are the therapeutic guidelines. The purpose of treatment is both the elimination of pain and prevention of blindness or other vascular complications and may be required for 5 years or longer.

Immune Complex–Mediated Vasculitis

The immune complex–mediated vasculitis are a heterogeneous group of small-vessel vasculitides that universally involve the skin, arteritic involvement of small vessels (particularly postcapillary venules), and leukocytoclasis. Diseases in this group include hypersensitivity angiitis, Henoch-Schönlein purpura, and cryoglobulinemia vasculitis. These syndromes appear to be immune complex–mediated and may be triggered by a foreign antigen, which is often not identified. Therapy is concentrated on identification and elimination of inciting antigens. Glucocorticoid and immunosuppressive drugs and plasmapheresis are commonly used in treatment.

Behçet Disease

Behçet disease is a systemic vasculitis affecting mostly East-Asian and Mediterranean populations and usually presents with oral and genital ulcers in the third decade of life. Ocular inflammation, such as anterior uveitis or panuveitis with posterior chamber involvement typically follows mucocutaneous symptoms. These aphthous-like ulcers are characteristically punched out, with or without surrounding erythema, and covered with a pale pseudomembrane. They are frequently the first symptom of the disease. Primarily, these painful lesions occur singly or in clusters on the lips, gingiva, buccal mucosa, and tongue and less frequently on the palate and in the oropharynx. The genital ulcers are similar but are deeper and larger. Healing occurs in a few days to weeks and some scarring results. Uveitis is seen in 50% of patients, and loss of sight occurs in 25%. Genetic studies have shown a strong association with human leukocyte antigen (HLA)-B51 gene. The diagnosis is also supported by positive pathergy test (an erythematous papule larger than 2 mm at the prick site 48 hours after the application of a 20- to 22-gauge sterile needle, which obliquely penetrated avascular skin to a depth of 5 mm). Aseptic neutrophilic infiltration causes the papule and is due to neutrophil hyperreactivity.

The cause of the disease is not known, but a genetic component exists, and vessels of all sizes can be involved. Large vessel involvement occurs in about a quarter of patient with Behçet disease and constitutes the number one cause of mortality (38). Symptoms may occur simultaneously or months apart, and diagnosis is made by exclusion of other similar diseases. Local treatment for oral and genital ulcers is primarily through the use of corticosteroid creams. Fever is treated with antipyretics or nonsteroidal anti-inflammatory medicines. Oral colchicine is a first-line systemic treatment for mucocutaneous involvement. Oral dapsone is used if colchicine fails. Local treatment for eye involvement includes topical mydriatic agents. Systemic steroids, cytotoxic immunosuppressive agents, and interferon alpha-2b are reserved for systemic disease, severe mucosal disease, and eye involvement. Antitumor necrosis factor α block agents have been used with success in severe and refractory eye inflammation (39) and mucocutaneous disease (40).

Cogan Syndrome

Cogan syndrome is a rare disease of young adults (median age, 22 years) characterized by Ménière-like auditory and

vestibular dysfunction, interstitial keratitis, and nonreactive tests for syphilis. Interstitial keratitis is a mononuclear cell corneal infiltrate resulting in eye irritation, erythema, and photophobia. The symptoms frequently begin after an upper respiratory infection. Histopathologic analysis of the inner ear has shown lymphocytic and plasma cells infiltrate in the spiral ligament and endolymphatic hydrops, degeneration in the organ of Corti, new bone formation and demyelination of cranial nerve VIII branches. Auditory and vestibular manifestations are usually bilateral and can include fluctuating hearing loss, vertigo, tinnitus, and aural pressure. These symptoms may resolve spontaneously and reappear months later. The hearing loss is progressive and severe and usually associated with decreased or absent vestibular responses on caloric testing. Bilateral deafness results in 50% of the cases. The ear symptoms may precede or follow the ocular disease by several years. Cogan syndrome is accompanied by a large- or medium-vessel systemic vasculitis in about 10% of the cases. Proximal aortitis with valvular involvement was found in up to 10% of the patients with Cogan syndrome. Pathologic features suggest end-organ–specific autoimmune mechanisms rather than vasculitis damage to the inner ear. Hearing outcomes are improved with early initiation of systemic corticosteroid treatment, so early diagnosis is critical. Permanent visual loss rarely results from this disease unless ocular inflammation involves the posterior segment. Interstitial keratitis is treated with topical steroids. Systemic steroids and occasionally immunosuppressive agents are used to treat the otologic symptoms. Cochlear implantation is successful after loss of hearing.

Kawasaki Disease

Kawasaki disease, also known as mucocutaneous lymph node syndrome, is a disease involving the pediatric age group, and it is the most common cause of acquired heart disease in children in the developing world. The cause is unknown, but epidemiologic data suggest an infectious cause. Clinical characteristics include fever, conjunctivitis, red and dry lips, erythema of the oral mucosa, strawberry tongue, polymorphous truncal rash, desquamation of the fingers and toes, and cervical lymphadenopathy. Although cervical adenopathy is the least common clinical feature in US cases, though it is more common in Asia (US occurrence is roughly 40%, in Asia cervical adenopathy is seen in 50% to 75% of patients), this disease must be considered in febrile children with cervical lymphadenopathy unresponsive to antibiotics without an alternative diagnosis. In 20% to 25% of untreated children, coronary artery dilation or aneurysms develop, and a small percentage die of myocardial infarction due to thrombosis or rupture of coronary aneurysms, usually within 2 to 12 weeks after the onset of the disease. Treatment with IV Ig and aspirin in the first 10 days of illness reduces the incidence of coronary abnormalities by 10-fold. Addition of methylprednisolone as a third therapy may be used if coronary artery abnormalities are still a possibility.

Kikuchi Disease (Histiocytic Necrotizing Lymphadenitis)

Kikuchi-Fujimoto disease is a histiocytic necrotizing lymphadenitis, is a rare, idiopathic, usually self-limited disease characterized by cervical lymphadenopathy and constitutional symptoms. The pathogenesis of Kikuchi disease is unknown; however, infectious and autoimmune etiologies have been proposed. The clinical course and histology favors an immune response of cytotoxic T cells and histiocytes to an unidentified infectious agent. Multiple agents were proposed, such as Epstein Barr virus, human immunodeficiency virus (HIV), parvovirus B19, human herpesvirus VI, human herpesvirus VIII, *Yersinia enterocolitica*, and *Toxoplasma*. Kikuchi disease has similar histologic features with SLE. In addition, both diseases share gender and age distribution. Kikuchi disease has been reported in association with SLE or before a diagnosis of SLE is made. The typical patient is a young Asian female. The prevalence of Kikuchi disease among patients with lymphadenopathy ranges between 0.5% in Saudi Arabia and 34.7% in Korea, with female to male ratio ranging from 1.26:1 to 1:4. The most common presentation is acute cervical lymphadenopathy (80%) associated with low-grade fever and flu-like prodrome. Fatigue and joint pain was reported in 7% of the cases, skin rash (10%), hepatosplenomegaly, leukopenia (43%), elevated acute-phase reactants (40%) and anemia (20%) (41). The lymph nodes are firm and mobile and about 2 cm in diameter; they are not fluctuant or draining. The course is usually benign and can last anywhere between a couple of weeks to 6 months. Few cases of complication from heart failure, infection, meningitis and macrophage activation syndrome have been reported. Kikuchi disease is diagnosed by excisional lymph node biopsy done after more common causes for cervical lymphadenopathy are excluded, such as mononucleosis, sarcoidosis, syphilis, SLE, tuberculosis, and hematologic malignancies. Laboratory tests might reveal granulocytopenia, atypical lymphocytes, elevated acute-phase proteins and LDH. Appropriate radiographic studies to look for tuberculosis, malignancy, or other possible disease are reasonable. The histology of the lymph node typically follows three phases: proliferative phase with follicular hyperplasia and paracortical expansion of lymphocytes (B and T), monocytes, and histiocytes; followed by a necrotizing phase that shows extensive necrosis with distorted lymph node architecture without neutrophilic infiltrate and with histiocytes dominance; and the last phase, the xanthomatous phase or foamy cell phase, with the resolution of necrosis. The first-line of treatment is supportive with nonsteroidal anti-inflammatory drugs. Corticosteroids, IV Ig, and hydroxychloroquine have been used in recurrent or severe forms of disease (42,43).

GRANULOMATOUS DISEASES

A granuloma is a lesion produced by a defensive immunopathologic process. Initially, a circulating monocyte

acquires additional cytoplasm and organelles in the process of removing inflammatory debris. If the phagocytic mechanism fails, the cell becomes inert and immobile (i.e., epithelioid) and then becomes a relatively functionless multinucleated Langerhans giant cell with lymphocytes and eosinophils surrounding it. Fibroblastic proliferation occurs around the involved cells, forming a granuloma. Although some granulomatous diseases have known, and often infectious, causes, the cause of others remains poorly understood.

If a patient is first seen with a nonhealing ulcerative lesion, mucosal tumor, or mass in the head or neck, a biopsy is frequently performed to rule out neoplastic disease. The pathologist often reports only the presence of granulation tissue consistent with acute and chronic inflammation. The differential diagnosis may be lengthy, and the physician's first task is to determine whether the lesion is a localized disease process or a regional presentation of a systemic disease. The investigation begins with a thorough history, with special reference to fever, night sweats, weight loss, loss of appetite, malaise, arthralgia, and other factors suggesting systemic disease. A history of recent travel to developing countries and the possibility of compromised immunity also are important factors.

A physical examination comes next and includes a search for cervical, axillary, or inguinal lymphadenopathy or hepatosplenomegaly. If the first biopsy is inadequate, a subsequent specimen should be obtained from the superficial margins or the depth of the lesion. Tissue also is sent for special stains and cultures. Preoperative consultation with the pathologist or microbiologist ensures proper collection and transportation of specimens. Further laboratory and radiologic workup depends on the findings of the history and physical examination. However, shotgun ordering of multiple studies targeted at rare diseases in a "rule out" fashion is not cost-effective.

Neoplastic Disorders

Langerhans Cell Histiocytosis (Histiocytosis X)

Langerhans cell histiocytosis (LCH) is the preferred term for these disorders of proliferation of mononuclear phagocytic cells. The unifying feature of the disorders classified under LCH is their histopathology. Histologically, LCH lesions are granulomatous and contain histiocytes, eosinophils, and lymphocytes. Giant cells, neutrophils, and plasma cells also may be present. In the early stages, the lesions are dominated by histiocytes, including Langerhans cells. As the lesions mature, necrosis, phagocytosis, and ultimately xanthomatous changes and fibrosis occur, and Langerhans cells are less common. The identification of Langerhans cells is necessary for diagnosis, and electron microscopy may be required to identify the characteristic inclusions known as Birbeck granules, X granules, or Langerhans bodies. On light microscopy, the pathologic Langerhans cells are similar to those found in the skin, in which these cells are involved in delayed hypersensitivity. The presence of Langerhans cells in the lesion of LCH with eosinophils and lymphocytes suggests an immunologic mechanism for the disease. By light microscopy, these lesions do not appear malignant; however, cells in the lesions have been shown to be clonal. Whether this is a reactive or malignant disease is still debated.

LCH has a number of recognized variants and can present a continuum of disease severity. The term *histiocytosis X* was coined in 1953 to unify the diagnoses of eosinophilic granuloma, Hand-Schüller-Christian disease, and Letterer-Siwe disease and to emphasize the unknown cause of these disorders. Other variants have been described, but this discussion is limited to the more common ones.

Traditional naming of this collection of disorders is based on the history of their first description in medical literature. Hand-Schüller-Christian disease, described in 1921, is the chronic disseminated form of LCH. Some investigators describe this process as the polyostotic form of eosinophilic granuloma. This entity occurs in children past infancy and in young adults, but it also is reported in the elderly. A classic triad, occurring in 10% of cases, consists of skull lesions, exophthalmos, and diabetes insipidus. Letterer-Siwe disease, described in 1933, is the acute disseminated form of LCH, which affects infants and children, age 3 years or younger. Extraskeletal involvement predominates. Eosinophilic granuloma, the localized form of LCH described in 1940, occurs in children and young adults. This disorder is characterized by osteolytic lesions in one bone (i.e., monostotic) or several bones (i.e., polyostotic), with a predilection for the frontal and temporal bones. The distinction between eosinophilic granuloma and the disseminated forms is helpful, but the distinction between Hand-Schüller-Christian disease and Letterer-Siwe disease does not affect treatment. Modern studies on LCH use classification schemes based on organ systems and sites of disease involved, rather than the traditional, historic classifications (44).

The annual incidence of LCH is about four per million, with the median age at diagnosis approximately 2 to 3 years. LCH is more common in males, and cases with multisystem involvement generally are initially seen in the first 2 years of life and are rare in adults. Half of the cases appear as a single bony lesion in patients older than 5 years old. Evidence exists that LCH is associated with a predilection to malignancy.

Many organ systems can be involved in LCH. As bone is the most commonly involved organ, with a predilection for the skull, the most common manifestation of the disease in the head and neck is skull lesions. The bony lesions of LCH are lucencies of the medullary bone, which look punched out on radiography, with no surrounding sclerotic reaction. Otitis media is the most frequent otologic finding in patients with LCH and is due to temporal bone involvement, particularly in the petrous ridge. Dental symptoms are due to mandibular involvement. Mandibular lesions

may be painful and cause swelling. The maxilla is involved less often. Gingival swelling is associated with cervical adenopathy. Skin involvement is common in the disseminated form and as a seborrheic rash that often involves the scalp and postauricular areas. Diabetes insipidus is common because of hypothalamic or pituitary involvement, and the thyroid also may be involved. Other organ symptoms commonly involved include the liver, lung, CNS, lymph nodes, and spleen.

Treatment depends on the extent of the disease. For isolated, accessible lesions in older children and young adults (eosinophilic granuloma), surgical excision is preferred. Radiation therapy is reserved for recurrences or inaccessible lesions. Isolated eosinophilic granulomas carry an excellent prognosis. Patients with systemic disease are generally treated with systemic chemotherapy. Vincristine, etoposide, and corticosteroids have proven to be effective chemotherapeutic agents, and with treatment, the mortality rate is approximately 20% (44).

Fibrous Histiocytoma

Fibrous histiocytoma most often develops as a painless mass lesion and is commonly found in sun-exposed skin and orbital tissues in the dermis and hypodermis but also can be found in deep soft tissues. In the head and neck, it has been found in the upper aerodigestive tract, salivary glands, and deep layers of the scalp and face. Age range is 1 to 70 years, with a male-to-female ratio of 2.5:1. The most common symptoms include nasal obstruction, epistaxis, dysphagia, and dyspnea. The lesions of fibrous histiocytoma are slow-growing nodules, and roughly one-third of tumors are multiple and metachronous.

The basic histopathology of fibrous histiocytoma consists of a biphasic cell population of fibroblasts and histiocytes with spindle-shaped cells with elongated nuclei arranged in a storiform (cartwheel) pattern. Some lesions show atypia and mitotic activity, although the histologic appearance does not completely correlate with clinical behavior. Metastasis is rare. Treatment of fibrous histiocytoma is local excision with clear margins.

Pyogenic Granuloma

Pyogenic granuloma is a polypoid capillary hemangioma, sometimes called lobular capillary hemangioma, which is seen on skin and mucosal surfaces. Histologically, pyogenic granuloma consists of circumscribed aggregates of capillaries arranged in lobules. These lesions are seen on the gingiva, most commonly the fingers, lips, face, nasal cavities, and tongue. Sixty percent of nasal lesions arise on the septum and can appear with epistaxis. Surgical excision is the treatment of choice; incomplete resection can lead to recurrence. These lesions are benign, and although they characteristically bleed intermittently, they are painless. In patients younger than 18 years, pyogenic granulomas occur predominantly in boys (82%), but a female predominance (86%) is found among patients 18 to 39 years old. It is probable that gender distribution is based on hormonal factors, as pyogenic granuloma is common, particularly in the gingiva, in pregnant women and shows marked regression with delivery. In this setting, these tumors are known as granuloma gravidarum.

Reparative Granuloma

The cause of reparative granuloma is unknown, but it is probably secondary to local trauma, such as a tooth removal. The peripheral form is a sessile or pedunculated mucosa-covered reddish or bluish mass arising from the gingiva or alveolar mucosa, and it is most commonly found on the anterior mandible. The central form is endosteal, usually anterior to the first molar in the mandible. Radiographically, the lesion appears as a lytic, expansile, unilocular cavity with well-demarcated nonsclerotic margins and a bony cortex, which is thinned but intact. Treatment consists of curettage.

Necrotizing Sialometaplasia

Necrotizing sialometaplasia is a lesion characterized by metaplastic epithelial cells lining small salivary gland ducts with the preservation of lobular architecture, unlike squamous cells or mucoepidermoid carcinoma. This process may be found wherever salivary tissue is present, but it occurs most often in the oral cavity, and the junction of the hard and soft palate is the most frequently involved site. This lesion is first seen as a deep-seated and sharply demarcated ulcer, but a nonulcerated swelling may be the only manifestation. Spontaneous resolution over the course of weeks to months is the rule. This entity is more common in persons who smoke and these lesions are often mistaken for oral carcinoma.

Sarcoidosis

Sarcoidosis is a systemic, idiopathic disease characterized by noncaseating granulomas in the afflicted areas. The disease usually occurs in the third to fifth decade, rarely before age 15 years, and is more common in women. It is relatively more common in African-Americans (annual incidence, 35 per 100,000) than in white Americans (11 per 100,000) and for unclear reasons the highest prevalence is estimated in Sweden (60 to 80 per 100,000), although this disease seen throughout the world. Sarcoid granulomas most often deposit in the lungs and intrathoracic nodes. Thirty to sixty percent of patients with sarcoidosis are asymptomatic, and incidental discovery by radiograph is a common presentation. One-third of patients have constitutional symptoms including weight loss, night sweats, fatigue, myalgia, and low-grade fevers. Symptomatic patients also may complain of dry cough, dyspnea, skin rash, arthralgia, or nervous system symptoms including vision changes. Generalized adenopathy occurs in 25% to 50% of the cases, and splenomegaly in 10%. Neural involvement occurs in 4% to 6% of these

cases, and 15% to 25% involve the orbit. Sarcoid may deposit in the subcutaneous "Darier-Roussy" nodules and can show isolated involvement or multiple system involvement. Sarcoidosis may present acutely with bilateral hilar adenopathy, erythema nodosum, and arthritis (poly- or oligoarthritis with periarticular soft tissue inflammation), this triad is called Lofgren syndrome, fever and uveitis may be associated. Lofgren syndrome is more common in Caucasians and has a good prognosis. Cardiac involvement is clinically present in 5% of sarcoidosis patients, but is considerably more common at autopsy, 67% of patients in Japan and 20% in United States (45). The most common clinically evident manifestations of cardiac involvement are conduction abnormalities, sudden death, and infiltrative cardiomyopathy. Diagnosis depends on the correlation of symptoms with radiographic, pathologic, or biochemical indicators.

The pathologic hallmark, the noncaseating epithelioid granuloma, is compact and demonstrates multinucleated giant cells, lymphocytes, and mononuclear phagocytic cells wrapped by fibroblasts and mast cells (Fig. 17.4). Typically no necrosis (caseation) is found. The predilection of the granulomas for lymph nodes and connective tissue can lead to the typical radiographic findings of hilar adenopathy, thickening of the septae between lobules, nodules, and generalized attenuation by diffuse interstitial lung involvement.

Diagnosis of sarcoidosis involves exclusion of other granulomatous diseases, particularly tuberculosis, and finding the typical granulomas on open or fine-needle biopsy. Laboratory evaluation includes chest radiography and skin tests for anergy and tuberculosis. When the diagnosis is established, it is important to evaluate the patient for the extent and severity of the disease, including possible CNS, cardiac, or ophthalmologic involvement (46). ACE has previously been used to monitor the course of the disease, but many physicians who treat these patients question the value of this test. ACE is elevated in 40% to 90% of sarcoidosis patient and it correlates with active pulmonary disease. It is produced by alveolar macrophage and epithelioid cells present in granulomas as a response to an ACE-induced factor released by T lymphocytes. More recently, serum and bronchial washing levels of interleukin (IL)-12 and bronchial washing levels of macrophage inflammatory protein 1α and 1β have shown promise as markers of disease severity (47). Nuclear scanning is occasionally used; it may reveal the typical pattern of uptake in sarcoidosis: the "panda sign" due to increased uptake in lacrimal and parotid glands and the lambda sign due to increased uptake in paratracheal and hilar lymph nodes.

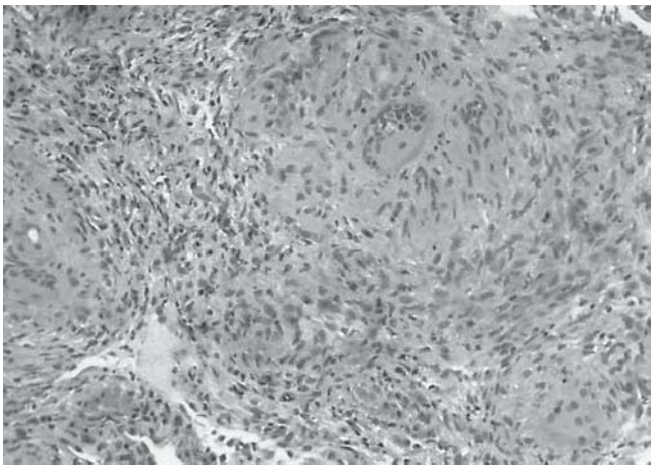

Figure 17.4 Sarcoidosis. Lung biopsy shows noncaseating granulomas with giant cells (hematoxylin and eosin stain; original magnification, 310×).

Although the cause of sarcoidosis is not known, recent evidence suggests a fivefold increased familial relative risk and possible linkage to chromosome 6 and specific HLA genes. Sarcoidosis is thought to be a result of host and environmental factors interacting to create an overexuberant T-cell–mediated response, but neither the host susceptibility nor the environmental triggers have been defined (46). The immunopathogenesis of noncaseating epithelioid granuloma, the hallmark of sarcoidosis, is believed to be a three-step event. The first step is lymphocytic alveolitis, a process driven by CD4+ Th1 lymphocytes being activated by antigen presenting cells. The second step is granuloma formation by local proliferation of Th1 lymphocytes, accumulation of macrophages and Langerhans-type cells surrounded by fibroblasts, and collection of more lymphocytes interweaved in bands of collagen. The third step is granuloma resolution.

Head and neck manifestations occur in 10% to 15% of patients, and the various manifestations may be the presenting disorder (48). Cervical adenopathy is present in nearly half of the patients with sarcoidosis. The typical yellow submucosal nodules or polyps of sarcoidosis may deposit anywhere in the upper respiratory tract. In the larynx, they usually deposit in the supraglottic larynx. Dysphonia, dyspnea, and dysphagia are the usual symptoms. Pathognomonic of laryngeal sarcoid is a diffusely enlarged, pale-pink, turban-like epiglottis. Lesions in the orbit include orbital masses, lacrimal swelling, and uveitis. Parotid swelling occurs in approximately 6% of patients, with or without facial nerve involvement. Parotitis, uveitis, facial paralysis, and fever are known as Heerfordt disease or uveoparotid fever. Sinonasal tract symptoms include nasal obstruction, edema, epistaxis, crusting, and nasal mass (49). Additionally, epiphora from lacrimal obstruction and anosmia have been described. Lupus pernio describes a purplish rash involving primarily the nose and cheeks, and it is a poor prognostic sign. Otologic involvement is rare, but sarcoidosis can involve structures of the ear. Middle ear dysfunction is usually due to eustachian tube involvement. Sensorineural hearing loss has been reported, likely due to meningeal inflammation, and tonsillar, pharyngeal, and cranial nerve involvement are other reported head and neck manifestations.

The natural history of the disease is variable. Most patients regress spontaneously (60%) or with corticosteroid treatment (20%); the severity of the disease can wax and wane, yet some succumb to the disease, particularly the pulmonary, CNS, and cardiac manifestations. Negative prognostic factors include age older than 40 years, chronic uveitis, nasal mucosal involvement, hypercalcemia, nephrocalcinosis, decline in pulmonary function, and cardiac and CNS involvement. Other negative prognostic factors include chronic disease (more than 2 years of systemic disease) and chest radiograph findings beyond hilar adenopathy (46). In the United States, the prognosis for those of African descent is worse than that for whites. In Japan, the patients die of cardiac sarcoidosis, whereas in United States pulmonary disease is the number one cause of mortality. Treatment is the use of oral corticosteroids, which improve pulmonary function and radiographic appearance, yet this treatment does not change long-term disease progression. Thus corticosteroid treatment is used sparingly to avoid long-term side effects. Steroid-sparing effect was showed with methotrexate and chloroquine. A relatively recent phase II trial demonstrated mild improvement in pulmonary function tests in patients treated with infliximab (50).

Gout

The arthritis of gout is episodic, self-limited, usually monoarticular, and a result of monosodium urate crystals deposition in and around the tissues of joints usually in association with hyperuricemia, a common metabolic abnormality. Definitive diagnosis is by microscopic examination in either joint fluid or a tophus that reveals negatively birefringent monosodium urate needles. According to the Third National Health and Nutrition Examination Survey, the prevalence of gout is 2.7 cases per 100 and rises to 9% in men older than 80 years (51). Head and neck involvement, although rare, usually is manifest as gouty arthritis or tophaceous deposits. The most common site of gouty arthritis in the head and neck is the cricoarytenoid joint that, depending on the position of fixation, produces pain, dysphagia, hoarseness, aspiration, stridor, and possible airway compromise. Tophi in the head and neck are usually painless and classically involve the helical rim of the pinna. Treatment of gout involves two major considerations: (a) treatment of acute attacks and (b) prophylaxis to prevent flares and long-term sequelae, such as chronic tophaceous gout. In the absence of contraindication, nonsteroidal anti-inflammatory drugs are the first-line therapy for acute attacks, although more often than not corticosteroids, regional or systemic, are necessary to control the attack. Colchicine in low dose (0.6 mg daily or BID) is an appropriate treatment for prophylaxis of recurrent attacks. Uric acid lowering therapy should be initiated only after total resolution of the acute inflammatory phase. Otherwise, it can worsen acute gout by mobilizing urate crystal from tophi. Allopurinol (most popular) and febuxostate (newer) are two commonly used urate lowering therapy.

Infectious Diseases

Bacterial Infections

Cat-Scratch Disease and Bacillary Angiomatosis

Although cat-scratch disease and bacillary angiomatosis are caused by the bacteria *Bartonella henselae* (belonging to the Rickettsiaceae family), they are associated with different histopathologic lesions and clinical pictures. *B. henselae* can be recovered from about 50% of cats, which may serve as the reservoir. This agent is an intracellular, pleomorphic, gram-negative bacterium, turning black or dark brown on the Warthin-Starry silver stain.

Cat-scratch fever is generally a self-limited regional disease, often seen in children. Fifty percent of patients first present with axillary, cervical, or submandibular lymphadenopathy that usually involve only one lymph node with erythema of the overlying skin. A mild fever is common. Fifty-five to ninety-four percent of patients exhibit a cutaneous lesion at the site of inoculation by a cat scratch or bite 3 to 14 days after exposure. A less common presentation occurs after conjunctival inoculation, causing Parinaud oculoglandular syndrome (red, tender, inflamed eye, possible conjunctival nodules, fever, and a preauricular lymphadenopathy). Uncommonly, the disease is complicated by liver, spleen, bone marrow, or lower respiratory involvement. CNS complications, including neuroretinitis, can also occur but are generally self-limiting. Approximately 25,000 cases of cat-scratch disease are diagnosed per year and are seen in the United States. Diagnosis is based on a history of cat exposure, the presence of a primary inoculation site, regional adenopathy, and histologic features of cat scratch (supportive and necrotizing granulomatous lymphadenitis with stellate microabscesses) in an excisional biopsy. Warthin-Starry silver staining of the tissue may reveal intracellular bacilli. Two types of serologic tests are available, indirect fluorescence assay and enzyme immunosorbent assay. Titers greater than 256 (titer is the reciprocal of the dilution) are highly suggestive of an active infection. Lower titers can be associated with false-positive results due to cross reactivity with other *Bartonella* species. Culturing the organism from tissue samples remains very difficult. Some centers use DNA detection of the organism after polymerase chain reaction (PCR) signal amplification for diagnosis.

Treatment is supportive, with incision and drainage reserved for abscesses that form in 5% to 10% of patients. Azithromycin is usually used as a 5-day therapy, but disappearance of the lymphadenopathy within 1 to 2 months is expected regardless of therapy. Rifampin and trimethoprim–sulfamethoxazole are often used as an alternative therapy.

Bacillary angiomatosis occurs predominantly in patients infected by the HIV. This disease presents as vascular

cutaneous papules and subcutaneous nodules or masses. Bacillary angiomatosis can involve other organs, causing hepatic peliosis, splenitis, osteomyelitis, and bacteremia. The clinical lesions can be confused with Kaposi sarcoma.

Bacillary angiomatosis may involve the mucous membranes of the nose, oral cavity, pharynx, larynx, bronchi, or conjunctiva. The causative agent is believed to be *B. henselae* and, to a lesser degree, *Bartonella quintana*. The disease caused by *B. henselae* is associated with exposure to cats and cat fleas, whereas the *B. quintana* cases are associated with louse exposure, poverty, and homelessness. The histopathology of bacillary angiomatosis is somewhat different from that of cat-scratch disease. In bacillary angiomatosis, lesions show ectatic vessels lined by plump, cuboidal endothelial cells that may show marked pleomorphism and mitotic activity that may be confused with malignancy. The organisms are best observed within the lesion Warthin-Starry or Grocott methenamine silver staining (52). The lesions respond well to erythromycin, clarithromycin, or doxycycline; rifampin is added for CNS involvement and life-threatening situations. If untreated, this disease is progressive and can prove fatal.

Brucellosis

Brucellosis (undulant fever, Mediterranean fever, Malta fever) is caused by an aerobic gram-negative coccobacillus. It is a zoonotic disease transmitted to humans from infected cattle, pigs, goats, elk, and bison, or from their dairy products. In the United States, most reported cases are due to ingestion of unpasteurized goat milk products from Mexico, or occupational exposure to infected animals. After exposure, the *Brucella* sp. bacteria enter the lymphatic system and replicate intracellularly in regional lymph nodes before disseminating hematogenously. The bacteria proliferate in the reticuloendothelial system and cause noncaseating granulomas in the involved tissues. Fatigue, sweating, chills, malaise, headache, backache, and arthralgia are common ailments, and this disease should be considered in the diagnosis of fever of unknown origin. Diagnosis is based on exposure history and serology using ELISA or agglutination tests. Newer PCR techniques are very sensitive, but culture of the organism remains the gold standard. The microbiology laboratory must be notified because long incubation periods are required (53). Doxycycline and rifampin for 6 weeks or doxycycline with 2 weeks of streptomycin/gentamicin are the treatments of choice (54). It is important to monitor patients closely after treatment completion as up to 10% of them will relapse.

Rhinoscleroma

Rhinoscleroma, sometimes called as "Balkan leprosy," is caused by *Klebsiella rhinoscleromatis*, a gram-negative bacterium. This disease is uncommon in the United States but is seen in the Middle East, Latin America, and Eastern Europe. It usually involves the nose and paranasal sinuses, but the larynx, ear, trachea, and bronchi can also be involved (55). The natural course of the disease is progression through three stages: catarrhal or atrophic, characterized by purulent rhinorrhea and mucosal crusting; granulomatous or hypertrophic, characterized by nasal mucosal granuloma and hyperplasia with bleeding and cartilage destruction; and fibrotic, which leads to nasal, laryngeal, and tracheobronchial tree stenosis. Diagnosis is based on finding the characteristic "honeycomb-color" crusting in the nose of patients, history of travel to endemic countries, and culturing of the organism; although only 50% of lesions will be culture positive (56).

Histologically, the submucosa demonstrates mixed inflammation, including characteristic Mikulicz cells (histiocytes with clear to foamy cytoplasm) during the granulomatous stage, when diagnosis is usually made. If numerous, the bacteria can be seen by hemalum-eosin staining, but a tissue Gram stain (e.g., Brown-Brenn) or a silver stain may be required to confirm the diagnosis. Long-term tetracycline is the standard treatment and occasionally surgical intervention is warranted for laryngeal obstruction during the florid or fibrotic stage.

Tuberculosis

Members of the genus *Mycobacterium* are a group of aerobic, nonsporulating, bacteria that are slow growing and have high cell-wall lipid content that makes them acid-fast on staining. *Mycobacterium tuberculosis* causes the vast majority of human tuberculosis. Tuberculosis is the second leading cause of infectious death in the world, leading to 2 million deaths per year. Up to one-third of the world's population is infected, and 9 million new cases occur annually (57). In the United States, the incidence has fallen every year since 1993. In 2009, 11,545 cases were reported, with a risk 11-fold higher in the foreign-born citizens compared to US-born individuals. Eighty percent of these cases were pulmonary. This disease is most frequent in geographic and demographic groups where AIDS is prevalent, notably among inner city African-American and Hispanic males between 25 and 45 years of age. An estimated 11% of the tuberculosis patients in the United States are coinfected with HIV. *Mycobacterium tuberculosis* is generally transmitted by inhalation of airborne droplets, which can remain aerosolized for hours. Other modes of transmission are rare. Tuberculosis is relatively rare in the head and neck. About 5.6% of people in the United States are tuberculin (partial-purified derivative—PPD) skin test positive, suggesting exposure to the bacteria. Almost 90% of these patients are asymptomatic, but the disease may develop at any time during their lives if left untreated. In many of these cases, the bacteria lie dormant in small numbers, unless the person becomes immunocompromised. This population represents the natural reservoir for the disease.

The pathogenesis is highly variable, and latency from exposure to clinical symptoms can be long. Initial pulmonary infections occur largely unchecked after inhalation until cell-mediated immunity is established from

3 to 9 weeks. At this point, the tuberculin skin test becomes positive, and the bacteria may have spread both regionally to lymph nodes and systemically. Granuloma formation results from the cell-mediated response to the infected loci and the original pulmonary lesion (Ghon focus) often heals. Reactivation later occurs in approximately 10% of these patients, mostly during the 1st year after exposure and often because of a reduction in host immunity. Infectivity is greatest in patients with positive sputum samples, lung cavitary disease, or tuberculosis of the larynx. Health care workers should be aware of the occupational risk of exposure; early identification of infected individuals is necessary for appropriate isolation precautions to be implemented.

A PPD skin test is considered positive if it causes a 15 mm or larger induration in normal hosts, a 10 mm or larger induration in high-prevalence groups (inmates, homeless, recent immigrants, etc.), and a 5 mm or larger induration in HIV-positive individuals, organ transplant recipients, or other groups of patients with defects of cell-mediated immunity. Unless a patient has been treated, a positive PPD test implies the presence of a few viable bacilli and the potential for reactivation. In addition to tuberculin skin testing, the diagnosis of latent tuberculosis can now also be made with one of two *in vitro* assays; the QuantiFERON-TB Gold In-Tube and the T-Spot.TB assays. These assays use the patient's whole blood and measure the lymphocytes release of interferon gamma in response to tuberculosis antigens. They are specific and sensitive, avoid the need for a follow up visit, and notably are not affected by BCG vaccination, but they are expensive (58).

Fine-needle aspiration cytology is useful in evaluating tuberculous lymphadenitis, but this technique has limitations, particularly when acid-fast bacilli cannot be found on smears. Nucleic acid amplification can identify mycobacterial DNA or RNA from specimens, particularly sputum, but also from tissue aspirates, with better sensitivity and specificity than direct microscopy (59). These tests take approximately 6 hours. All patient specimens should be sent for mycobacterial culture. Culture takes longer than a nucleic assay to give a result, but it is essential for drug susceptibility testing, especially with the rising multidrug resistant tuberculosis cases.

Tuberculosis has many different manifestations, which may include constitutional symptoms. Cervical lymphadenopathy is the most common form of head and neck involvement. Nodes are multiple, matted, bilateral, firm, and generally nontender. They frequently involve the posterior triangle and supraclavicular area. If a nonanergic patient with cervical lymphadenitis has a negative PPD test, tuberculosis is unlikely because 98% of patients with cervical lymphadenitis due to tuberculosis have a positive skin test. Fine-needle aspiration is helpful in reaching a diagnosis. A chest radiograph should always be obtained, and a neck computed tomography (CT) scan and ultrasound should be considered. CT findings include a multiloculated low-density nodal mass with enhancing rims and normal fascial planes. The walls of the nodal mass also are thicker than those found in malignant disease. As necrotic caseation and suppuration continue the ultrasound image changes to a low echogenic mass with nonhomogeneity and with further progression, abscess formation spreads into adjacent subcutaneous tissues. Excisional biopsy should also be considered and will reveal the characteristic granulomas (Fig. 17.5). The most common laryngeal symptom is hoarseness, but odynophagia, dysphagia, and stridor are not uncommon. A high index of suspicion must be maintained for laryngeal tuberculosis in patients infected with HIV. Before the antibiotic era, laryngeal involvement was common, but now it is rare and seen in less than 1% of all tuberculosis cases. In these patients, lesions can be seen throughout the larynx and can vary in appearance such as edema, hyperemia, nodularity, ulcerations, and obliteration of anatomic landmarks. Specifically, the epiglottis can be markedly edematous (turban-shaped), and can resemble polypoid corditis. Exophytic lesions can often be mistaken for laryngeal carcinoma.

Otologic involvement begins with granulomas appearing as thickened hyperemic spots on the tympanic membrane, which coalesce to form multiple perforations. These perforations painlessly drain a thin watery discharge. Granulation tissue then increases, with the discharge becoming thick and cheesy, often because of pyogenic bacterial superinfection. Mastoiditis may ensue, with intracranial extension. Mastoid imaging typically does not show bony destruction and sclerosis as the process is relatively acute. Generally, examination reveals middle ear granulation with erosion of the ossicles. Postauricular fistula may occur, and preauricular adenopathy is common (60). Mastoidectomy should be reserved for concurrent mastoiditis.

Other head and neck sites can be involved. Nasal infection is manifested by obstruction and rhinorrhea. Mucosal

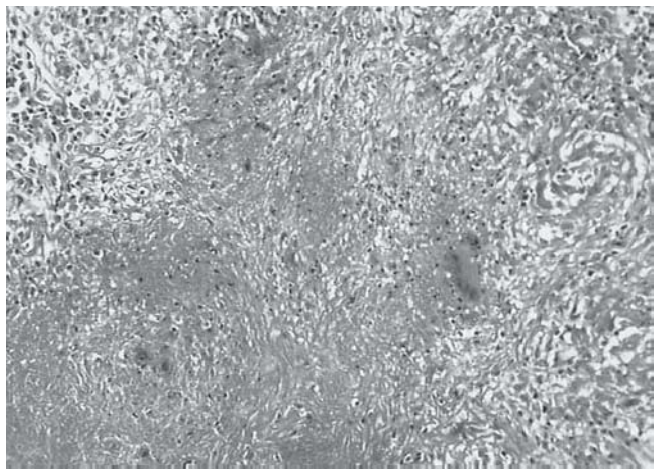

Figure 17.5 Tuberculosis. Lymph node reveals necrosis surrounded by Langerhans giant cells, epithelioid histiocytes, and lymphocytes (hematoxylin and eosin stain; original magnification, 310×).

granulomas are seen, and septal perforation can occur. Tuberculosis can cause oral ulceration. Nasopharyngeal and oropharyngeal tonsillar tissue may be infected, and salivary glands may become involved (62).

Treatment for tuberculosis is directed by organ site involved, culture, and drug susceptibility. Patients with suspected or confirmed pulmonary or laryngeal tuberculosis must be placed in respiratory isolation until no longer infectious. There are currently four recommended regimens for patients with confirmed or suspected tuberculosis. The usual first option is a four drug daily regimen of isoniazid, rifampin, pyrazinamide, and ethambutol for the first 2 months (the intensive phase). A repeat smear and culture at the end of the intensive phase of treatment will determine the regime used in the continuation phase of treatment, which is usually a 4-month course of isoniazid and rifampin. In certain cases, the treatment could be extended to a total of 9 months (61). The current incidence of resistance to at least one drug in the United States is 12%, and 1% for multidrug resistance (resistance to at least isoniazid and rifampin). This makes following cultures and susceptibility testing important to make sure that the usual drug combinations are effective. All tuberculosis cases should be reported to the local public health department, and patients with tuberculosis should be tested for HIV (62). Lymph node excisions *en bloc* may be necessary for fluctuant or chronically draining nodes.

Nontuberculous Mycobacteria

Nontuberculous mycobacteria are usually less virulent than *M. tuberculosis*; however, they also are less responsive to standard antituberculous drugs. They are generally free living, ubiquitous organisms in the environment, and can colonize the upper respiratory tract making repeated positive cultures more significant than a single culture. The usual routes of transmission are from soil to the oral cavity, the respiratory tract, or the eye. Incubation periods are long, up to 5 years. The prevalence and virulence of nontuberculous mycobacterial disease, especially the *Mycobacterium avium-intracellulare* complex (MAC), have increased in the HIV population in whom these pathogens are considered opportunistic. In AIDS patients with low CD4 lymphocyte counts, the disease can become systemic. Oral ulcerative lesions, fever, and weight loss are common features of disseminated disease. *Mycobacterium kansasii* is the second most common atypical mycobacteria affecting the pulmonary system especially in the elderly, and is often recovered from tap water.

Mycobacterium scrofulaceum most often cause lymphadenitis (scrofula) in children younger than 6 years. The lymphadenopathy is most commonly cervical, predominantly in the preauricular, submandibular, or anterior cervical areas. Enlargement is slow, and eventually the skin becomes involved, and a draining tract develops. Scrofula in children also can be commonly caused by MAC (more than 80%) and less commonly by *M. kansasii*. Tuberculosis itself as a cause for cervical lymphadenopathy is rare (less than 10%) in the United States. Nontuberculous mycobacteria like *Mycobacterium fortuitum*, *Mycobacterium abscessus*, and *MAC* are rare causes of parotitis and mastoiditis, with a presentation similar to that of tuberculous mastoiditis, including chronic painless otorrhea, and exuberant middle ear granulation tissue.

Diagnosis is usually by culture and sensitivity testing of a biopsy specimen; typical detection of growth in cultures takes about 2 weeks, but identification of the species can take up to 4 weeks. Acid-fast staining may provide a presumptive diagnosis before positive culture results are available. Susceptibility testing is strongly desirable, but developing standard techniques have been difficult and unreliable. The use of nucleic acid probes and the PCR are becoming more common for both the rapid identification of mycobacterial species and the identification of drug-resistant strains. These novel techniques may shorten laboratory diagnostic time to days. Furthermore, a positive culture is seen only in about 50% of patients with scrofula, so a high index of suspicion is necessary for diagnosing a child with a pathologic diagnosis of granulomatous inflammation. A PPD test is often weakly positive (induration ranging from 5 to 12 mm).

Pediatric patients with scrofula are treated by excisional biopsy when the nodes involved can be safely resected. Complete resection is usually curative and preferable because the time course of the disease is shortened (63). For fluctuant lesions, lesions with severe skin necrosis, and lesions close to the facial nerve or other critical structures, excisional surgery may have an unacceptable risk of complication. Conservative treatment with combination antimycobacterial drugs and wound care may be preferred. MAC infections with or without HIV is often treated with clarithromycin, rifabutin, and ethambutol. Even without treatment, localized disease will resolve, but the usual course of illness is long, and may result in undesirable scarring (64). Incision and drainage or multiple biopsies are contraindicated. Nontuberculous mastoiditis should be treated with mastoidectomy as they are less responsive to antibiotics.

Leprosy

Leprosy (Hansen disease) is still a worldwide problem, but less than 100 cases per year are reported in the United States, mostly in immigrants. The mode of transmission of leprosy is still unclear but is thought to be through a respiratory route. Cutaneous transmission appears to require prolonged contact to open lepromatous wounds. Leprosy is caused by *Mycobacterium leprae*, an acid-fast bacillus, which is an obligate intracellular parasite. Table 17.6 lists the common manifestations of leprosy (65). The bacteria are thermolabile, growing optimally between 27°C and 33°C, and divide slowly; thus the disease evolves slowly and involves primarily cooler peripheral tissues such as in the fingers, nose, testicles, feet, and earlobes. It leads to loss of peripheral sensation

TABLE 17.6 COMMON MANIFESTATIONS OF LEPROSY (65)

Hypopigmented or erythematous macules
Tuberculoid skin and nerve involvement with muscle wasting and anesthesia
Anesthetic plaques
Nerve thickening in the plaque vicinity
Mucosal nodules in the mouth and nose that ulcerate (especially anterior inferior turbinate)
Keratitis
Laryngeal ulcerations
Lymphadenopathy
Hyposmia
Atrophy of the anterior maxillary spine and maxillary alveolar process
Nasal collapse
Fish-mouth deformity
Facial nerve paralysis
Eyebrow and eyelash loss

and eventually traumatic mutilation. Early skin lesions vary from hypopigmented to erythematous macules with well-defined margins. Biopsy of the lesions is required to make the diagnosis. Involvement of the nasal cavity and paranasal sinuses may manifest before the clinical skin lesions (56). The Ridley-Jopling classification identifies different forms of the disease that are important to recognize for treatment purposes. They range from the tuberculoid form characterized by a few anesthetic, well-delineated macules or plaques and common peripheral nerve involvement to the lepromatous form with multiple nonanesthetic, symmetrical macules or papules, and neurologic involvement only late in the disease. The tuberculoid form is associated with a strong local T cell reaction that causes a positive lepromin skin test, and a low bacillary density. In contrast, the lepromatous form is characterized by a negative skin test and a heavy bacillary load. This latter form is associated with damage to various end organs, which for some of them can be the result of an immune complex–mediated reaction called erythema nodosum leprosum. Eye involvement causes pain, photophobias, glaucoma, and blindness. Laryngeal involvement results in stridor and hoarseness. The characteristic saddle-nose deformity is seen with involvement of nasal cartilages. Nasal congestion and epistaxis are common. PCR diagnostic techniques can be run on nasal smears, skin biopsy and blood specimens. Depending on the severity and type of disease dapsone alone or in combination with clofazimine and rifampin are used for a long duration.

Actinomycosis and Nocardia

Actinomycosis is a granulomatous infection caused by anaerobic or microaerophilic gram-positive filamentous bacteria called *Actinomyces* species. At least 30 different species have been described with *Actinomyces israelli* being the most common cause of human disease. *Actinomyces naeslundii*, *Actinomyces odontolyticus*, *Actinomyces meyeri*, and *Propionibacterium propionicum* are seen as well. Infection may follow dental manipulation, trauma, or gingival infection in patients with poor oral hygiene. Bacterial growth is facilitated by the presence of necrotic tissue and a foreign body. The three commonly described clinical forms are cervicofacial, thoracic, and abdominopelvic with about 50% of all actinomycosis being cervicofacial. Actinomycosis may occur virtually anywhere in the head and neck and has been described in the sinuses, mastoid, major salivary glands, and thyroid (66). Sixty-one percent of patients with cervicofacial infection have visible sinus tracts, and 40% have lymphadenopathy. Concurrent dental, sinus, and perimandibular disease is common, with or without pain and fever. The course of actinomycosis is typically indolent but progressive. Symptoms are often present for months before diagnosis is made or erroneously attributed to tuberculosis or cancer. Actinomycosis may also present as an acute suppurative infection with rapid progression to abscess formation. A suggestive purplish discoloration of the overlying skin may be seen in some patients. The infection does not respect fascial planes. Granuloma formation and frank suppuration of the larynx have also been reported with cicatricial scarring as noticeable possible long-term sequelae.

"Sulfur granules" are usually seen in exudates or on histologic examination, although this finding is not present in every case (Fig. 17.6). These granules are concretions of the organisms and neutrophils. They are hard, yellow particles measuring about 0.1 to 5 mm in diameter. Diagnosis is confirmed by culture incubated for 1 to 2 weeks in thioglycollate broth in a microaerophilic environment. On smear, Actinomyces are branching, filamentous organisms and should be differentiated from fungal hyphae, which are much thicker and less delicate (56).

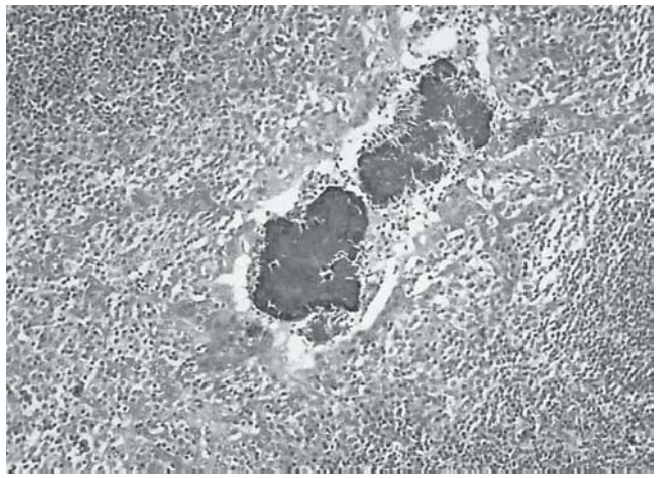

Figure 17.6 Actinomycosis. Tonsil exhibits colonies of *Actinomyces* organisms in the crypts (hematoxylin and eosin stain; original magnification, 310×).

The genus *Nocardia* includes more than 80 species. It is a member of the family Actinomycetaceae and shares morphologic features with *Actinomyces*. *Nocardia* spp. are opportunistic pathogens most commonly causing pulmonary disease in an immunocompromised host, although about 33% could be immunocompetent. It is not a part of the normal flora. The most common route of transmission is inhalational but, cutaneous *Nocardia* infection can be seen after trauma to the skin. This disease can appear as a localized pustule, cellulitis, abscess, or mycetoma. Actinomycetoma, usually caused by *Nocardia brasiliensis* are localized, chronic, indolent lesions that can grow quite large if untreated and should be differentiated from eumycetoma which are caused by fungi (67). The granules in a *Nocardia* actinomycetoma are white, in contrast to the yellow "sulfur granules" of actinomycosis.

Treatment of actinomycosis is by surgical debridement plus aqueous penicillin G administered intravenously for 2 to 6 weeks followed by 6 to 12 months of oral penicillin. Penicillin-allergic patients respond well to tetracycline or clindamycin. Wide excision is not required. Nocardia is treated by trimethoprim–sulfamethoxazole or imipenem but susceptibility testing should be requested as different species have variable resistance patterns.

Syphilis

Syphilis is a sexually transmitted disease caused by the spirochete *Treponema pallidum* and is reportable in the United States. On the decline since 1990, the disease incidence rebounded since the past decade, especially in the young men who have sex with men population. There were 11,181 reported cases in 2007. The disease passes through three stages. The primary stage is characterized by the development, typically on an average of 3 weeks after exposure (range 10 to 90 days) of a small red papule that gradually enlarges and evolves into a painless ulceration with indurated edges, the syphilitic chancre. Secondary syphilis develops about 4 to 10 weeks after the primary lesion. Patients often complain of malaise, fever, myalgias, and arthralgias. Lymphadenopathy and a maculopapular rash, especially on the palms and soles, can be seen (56).

An asymptomatic stage known as the latent phase, which can last up to 30 years, is characterized by a positive serologic reaction. The 1st year of the secondary stage is called early latent, and subsequently is the late latent phase. In about a third of patients, the latent stage can evolve into the tertiary stage of the disease with three main presentations: gummas, late neurosyphilis, and cardiovascular disease. Gummas are inflammatory granulomas characterized by an *intervening zone* containing epithelioid cells with indistinct borders and multinucleated giant cells, and a *peripheral zone* of fibroblasts and capillaries. They appear as soft masses that usually develop in the skin, bones, and liver on average 15 years (range 1 year to more than 40 years) after the initial infection; any organ can be affected. General paresis, a peculiar form of psychosis, and tabes are now very rare, but are classic manifestations of neurosyphilis. Aortitis is the characteristic form of cardiovascular syphilis. A devastating congenital form can be seen as a result of transplacental transfer. The multiple manifestations in the head and neck depend on the stage of the disease (68).

Syphilis is associated with otologic disease. Sensorineural hearing loss from either congenital or tertiary syphilis accompanied by fluctuating tinnitus and vertigo is termed otosyphilis. The exact pathologic mechanism is not known. The hearing loss starts in the high frequencies but can progress to bilateral profound deafness, with absent vestibular function. Screening patients with sensorineural hearing loss for syphilis is controversial. Although the yield is low, the potential reward is high because syphilis is a treatable cause of sensorineural hearing loss. Even though the spinal fluid is seldom positive for syphilis, often patients with otosyphilis are treated as neurosyphilis patients. In one study, 83% of treated patients preserved their hearing (69). Involvement of the middle ear with destruction of the ossicles can occur. The development of nystagmus upon the application of pressure to a sealed external auditory canal (Hennebert sign) suggests the presence of a fistula in patients with syphilis, presumably from fibrosis between the stapes footplate and the membranous labyrinth.

Mucosal head and neck structures also can be involved. Chancre formation in the oral cavity results from primary inoculation. Lesions of secondary syphilis can present as mucosal erosions on the nasal cavity, tongue and lips, hairy leukoplakia, oral lichen planus, or oral erythema multiforme. Gummas can be located in the oral cavity, pharynx, or larynx. Congenital syphilis can cause otosyphilis and radial scars (rhagades) of the tongue, palate, and lips. Nasal discharge is an early sign of congenital syphilis, while "Hutchinson teeth," which are notched, lack enamel, and are underdeveloped, occur in late congenital syphilis.

The diagnosis of syphilis is established by either direct visualization of the spirochete or more commonly by serology testing, as the organism does not grow in culture. Dark-field examination of tissue from lesions of primary, secondary, or tertiary syphilis demonstrates thin, delicate, corkscrew-shaped organisms but this study is only performed in a few laboratories now. Histologic examination, although not pathognomonic for syphilis, reveals a dense chronic inflammatory infiltrate with an abundance of plasma cells (Fig. 17.7). Early nodular lesions of tertiary syphilis can have minimal necrosis and sparse plasma cells with granulomas thus mimicking tuberculosis, sarcoidosis, or a deep mycosis (70). Two types of test are used for the serologic diagnosis of syphilis, nontreponemal tests such as the Venereal Disease Research Laboratory (VDRL) and rapid plasma reagin (RPR), and treponemal tests like the fluorescent treponemal antibody absorbed test, the *T. pallidum* passive particle agglutination assay, and various enzyme immunoassays. Due to their high sensitivity, the nontreponemal tests are used as primary screening tests; the RPR on serum and the VDRL on cerebrospinal fluid

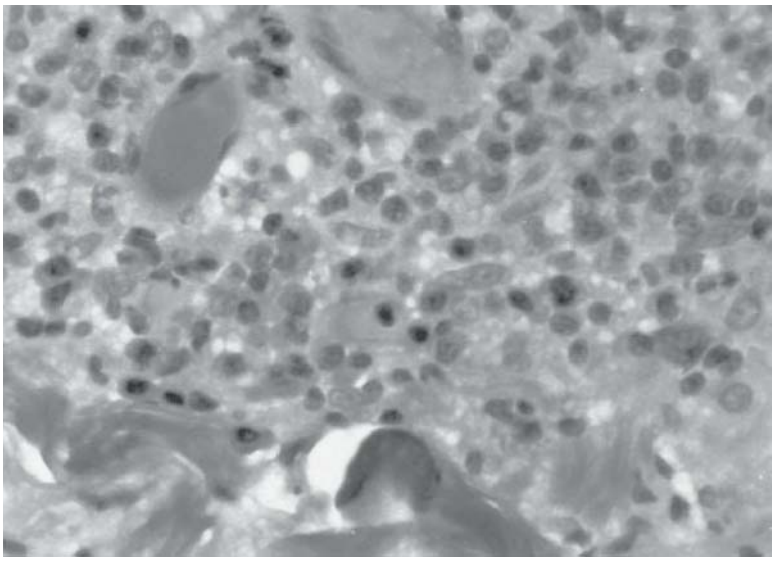

Figure 17.7 Syphilis. The skin of the neck shows typical, chronic, dense inflammatory infiltrate with abundant plasma cells (hematoxylin and eosin stain; original magnification, 340×).

(CSF). Because they usually correlate with disease activity, the results are reported quantitatively. However, many conditions can result in false-positive reactions, and a positive result needs to be confirmed with a treponemal test, which offers greater specificity. The magnitude of the seroreactivity with the nontreponemal tests tends to decrease or even disappear after treatment, while treponemal tests remain positive for the remainder of the patient's life in most instances (71). Clinical signs of neurosyphilis (i.e., cranial nerve dysfunction, meningitis, stroke, acute or chronic altered mental status, loss of vibration sense, and auditory or ophthalmic abnormalities) warrant further investigation and treatment. Laboratory testing is helpful in supporting the diagnosis of neurosyphilis; however, no single test can be used to diagnose neurosyphilis in all instances. CSF laboratory abnormalities are common in persons with early syphilis.

Benzathine penicillin given intramuscularly is the treatment of choice and curative in a single dose for the primary disease and early latent syphilis. Three weekly injections are recommended for the treatment of late latent syphilis or latent syphilis of unknown duration. Tertiary syphilis such as otosyphilis and neurosyphilis requires 10 to 14 days of IV penicillin. Steroids are used for improvement of hearing and reduction of vestibular symptoms. However, treatment differs for each stage and consideration should be given to sexual partner management (71). All positive cases should be reported to the state health department.

Tularemia

Tularemia is a rare disease caused by the gram-negative pleomorphic rod, *Francisella tularensis*. It is a complicated, highly virulent zoonotic agent. The natural reservoirs include hundreds of animals; especially important in human disease are ticks, cats, rabbits, and deer. Infection is due to direct inoculation by contamination of a wound or ingestion of uncooked meat or an arthropod bite. After an incubation period of 2 to 10 days, the patient exhibits severe illness with fever, chills, headache, and myalgia. Almost 60% to 80% have ulceroglandular disease. Isolated lymphadenopathy may be present in 3% to 15%. One distinct form of the disease is oropharyngeal tularemia due to ingestion of animal meat or contaminated water (72). These patients have fever, exudative pharyngitis, and cervical adenopathy. Diagnosis is confirmed with a serum agglutination test or ELISA tests to detect antibodies to the organism. A titer of 1:160 or higher is supportive of the diagnosis and patients are treated with a short course of streptomycin or gentamicin.

Fungal Infections

Histoplasmosis

Histoplasma capsulatum, a dimorphic fungus, is the causative organism of histoplasmosis. This entity most commonly occurs in the Ohio and Mississippi River valleys. It is spread by airborne particulate dissemination of soil contaminated with bird or bat guano, which supports luxurious growth of this mold. Pulmonary histoplasmosis may present as acute pneumonitis with mediastinal lymphadenopathy or a chronic cavitary infection. Progressive disseminated forms may involve the heart and CNS. Most infections are subclinical and have benign clinical courses. In endemic areas, by adulthood almost 80% have had this disease. However, infants, elderly or those who are immunocompromised (e.g., HIV infection) can often have the progressive disseminated form, which consists of granulomatous lesions spread throughout the body. Head and neck mucosal sites, including the lips, gingiva, tongue, pharynx, and larynx, are involved in 25% of disseminated cases (73). These lesions show firm, slowly enlarging, painful ulcers with heaped-up edges or a verrucous appearance and sometimes mimic carcinoma or tuberculosis. Sore throat, painful mastication, hoarseness, gingival irritation, dysphagia, and weight loss may

result. Granulomatous mediastinitis is characterized by massive enlargement of multiple lymph nodes that are often matted together and undergo caseation and necrosis. Diagnosis is facilitated by two types of tests, the detection by enzyme immunoassay of *Histoplasma* antigens in the urine, and the detection of specific serum antibodies by complement fixation and by immunodiffusion. The pathology often shows lymphohistiocytic aggregates and diffuse mononuclear cell aggregates forming granulomas. Methenamine silver or periodic acid-Schiff staining best demonstrates the ovoid shape yeast phase of the organism with narrow based budding. The culture of a swabbing of an ulcer centers or any tissue sample after 4 to 6 weeks of incubation will grow the mycelial phase of the fungus. Itraconazole is the usual treatment of choice for mild disease and the severe and CNS forms are treated with liposomal amphotericin B (74).

Blastomycosis

The causative organism of blastomycosis is the dimorphic fungus *Blastomyces dermatitidis*, which is contracted by inhaling the conidia of the organism disseminated in soil dust, or sometimes present in the home (attic, basement). Fungal reproduction of the yeast form occurs in the lungs and can cause an acute or a chronic form. Direct inoculation is a rare mechanism of infection. The endemic area for blastomycosis includes the entire central United States from the Gulf Coast to the Canadian border and extends into the southern parts of Manitoba, Saskatchewan, and Alberta. Manifestations range from the patient being asymptomatic to having acute pneumonitis with disseminated infection involving the skin, bones, and genitourinary system (esp., prostate, epididymis, and testes). Skin lesions exhibit proliferative verrucous growth with scarring. A common triad consists of cutaneous disease, pulmonary involvement, and constitutional symptoms. The face and extremities are common sites for skin lesions. Subcutaneous nodules are cold abscesses in the disseminated form. Oropharyngeal and laryngeal involvement is much less common than in histoplasmosis, although case reports of blastomycosis involving multiple sites in the head and neck such as the larynx, parotids, and paranasal sinuses can be found. The diagnosis of pulmonary blastomycosis is confirmed by sputum culture and microscopic examination of skin scrapings or biopsy of other involved sites. Unlike *Candida* and *Aspergillus* species, colonization does not occur with this fungus and hence visualizing this fungus is diagnostic of an infection. It grows well within 1 to 4 weeks. On a tissue methenamine silver stain, it appears as thick walled budding yeast with a broad base. Urine and serum antigen detection tests are sensitive and appear to correlate with disease activity and/or recurrence (75). Itraconazole is the treatment of choice for most cases of blastomycosis. Amphotericin B is reserved for immunosuppressed patients or CNS involvement (76).

Coccidioidomycosis

Coccidioides immitis, the agent of coccidioidomycosis, is a fungus endemic in southern Arizona, southern and central valley of California, southwestern New Mexico, west Texas and parts of Central and South America. As with histoplasmosis, most residents in endemic areas become infected as children. The disease is contracted by inhalation of the arthroconidia. In the lungs, the arthroconidia changes to a spherule which enlarges over time, matures and eventually ruptures releasing endospores, which can lead to hematogenous dissemination (77). A subacute illness known as Valley fever is seen with respiratory and systemic involvement, often lasting for weeks to months. Manifestations in the head and neck are rare but most commonly, as a result of dissemination, involve the skin, where lesions are first seen as nodules or erosions and can form draining sinus tracts. The mucous membranes, thyroid, eyes, orbit, trachea, temporal bones, facial skeleton, and larynx can also be involved (78). Some of the more severe forms of extrapulmonary infections are meningitis and vertebral osteomyelitis, which can have an acute presentation. Diagnosis is established by histology (the methenamine silver stain is the most sensitive), serology, and culture (the organism may take many weeks to grow). Patients are treated with fluconazole or itraconazole whereas amphotericin B is reserved for severe disease and azole failures (79).

Paracoccidioidomycosis, also called South American blastomycosis, is a disease primarily found in South America with almost 80% of infections occurring in Brazil. This disease is rare in healthy adults but can be serious in immunocompromised patients. The infective agent is the dimorphic fungus *Paracoccidioides brasiliensis*. Head and neck manifestations include the common involvement of the oral mucosa. The oral lesions are generally granulomatous in appearance but can be ulcerated (80), and the larynx also can be involved in the disease. Diagnosis is usually based on visualization of the organism in a biopsy of the involved tissue, culture of enlarged lymph node aspiration or serology. Histologically, the lesions are suppurative granulomas with lymphocytes, epithelioid cells, and giant cells. Azole antifungal agents and amphotericin B are effective treatments.

Parasitic Infections

Leishmaniasis

Leishmaniasis is a disease distributed worldwide, except Antarctica, caused by various species of *Leishmania*, obligate intracellular protozoans belonging to the family of Trypanosomatidae, and divided into subgenera *Leishmania* and *Viannia*. These parasites are transmitted as promastigotes by the bite of female sand flies (genus *Lutzomyia* in the Americas, *Phlebotomus* elsewhere). The promastigote enters mononuclear phagocytes in the skin, and multiplies and transforms in the macrophage cytoplasm into amastigotes. The infection can then remain asymptomatic or progress to one of the three characteristic forms of the disease: visceral

(causing kala-azar in its full blown form), cutaneous (the commonest), and mucocutaneous (about 1% to 5% of primary cutaneous forms can advance to this stage). The patterns of illness in large part depend on the tissue tropism of the particular *Leishmania* species. Lesions are the result of the cell-mediated immune response to the organism in targeted tissues. The cutaneous form most commonly occurs on the extremities, although the head and neck may be affected. Papules that progress to wet or dry ulceration with indurated borders and encrustation are characteristic. Mucocutaneous leishmaniasis, mainly associated with *Leishmania braziliensis* infection is also called espundia. Mucocutaneous leishmaniasis exhibits an initial lesion on the extremities and months to years later due to hematogenous or lymphatic dissemination, new lesions occur on the mucosal surfaces. Progressive inflammation and destruction of the soft tissues of the mouth, nose, pharynx, epiglottis, larynx, and trachea may occur with attendant disfiguration. Ulceration can lead to nasal septal perforation and mucosal bleeds. Internal destruction can be considerably more extensive than the external damages. This form of the disease is seen primarily in South America (81).

Diagnosis of all forms is established by microscopic visualization of the intracellular organism in a biopsy or skin scrapings. The histology findings range from well-formed granulomas with numerous lymphocytes and a few identified amastigotes to an abundance of parasite-containing tissue macrophages and few lymphocytes. The organism can be revealed with Giemsa, hematoxylin-eosin or Wright stain. The organism can also be cultured in special media and newer PCR-based assays are now available (82). Patients traditionally have been treated with pentavalent antimonial (Sb^V) compounds: sodium stibogluconate and meglumine antimonite. Liposomal amphotericin B and pentamidine are alternate agents. Miltefosine has been a promising oral agent. All these drugs can be associated with substantial toxicities. Various azole antifungal agents appear efficacious as well in cutaneous leishmaniasis (83,84).

Myiasis

Myiasis, often seen in a returning traveler, is a condition caused by the infestation by maggots transmitted in Mexico, Central and South Americas by the botfly (*Dermatobia hominis*) and in tropical Africa by the tumbu fly (*Cordylobia anthropophaga*). Myiasis may be nonfuruncular when present in the oropharynx or nasopharynx, or furuncular when in the skin. Patients typically note an insect bite which enlarges to a nodule (1 to 3 cm in diameter) that can be associated to a serosanguineous discharge and a crawling sensation. Diagnosis is made clinically or by microscopic examination. Treatment consists of surgical removal of the entire larva (85).

Toxoplasmosis

Toxoplasma gondii is a widely distributed intracellular protozoan parasite that infects various mammals, including sheep, pigs, cats, rodents, cows, deer, and humans, and causes toxoplasmosis. The cat is the primary host, where sexual reproduction of the parasite occurs. Human infection with *T. gondii* occurs through ingestion of oocyst-containing cat feces or poorly cooked infected lamb or pork. In the human intestine, the sporozoites from the oocysts or the bradyzoites from the tissular cysts are released, and invade various tissues (especially muscles, heart, liver, spleen, lymph nodes, and CNS) where their intracellular reproduction yields tachyzoites that further disseminate throughout the tissues of the body where they eventually form bradyzoites-containing cysts. In the United States, almost 11% of adults have been exposed to this organism. Primary infection is asymptomatic in 80%. Congenital toxoplasmosis can occur from vertical transmission of tachyzoites from an infected mother, while in the immunocompromised host, secondary disease can result from the reactivation of the cysts particularly in the CNS, but also in the lungs and myocardium. This is a feared opportunistic infection in the AIDS population with very low lymphocyte count and is suspected whenever a patient with prior evidence of toxoplasmosis infection presents with multiple nodular or ring-enhancing brain lesions with edema or mass effect. Primary toxoplasmosis most commonly presents as bilateral painless cervical adenopathy. Pharyngitis, rash, fever, fatigue, and hepatosplenomegaly can be seen. The likelihood of transmission and the severity of disease in congenital toxoplasmosis is greater as the pregnancy advances. Although generally normal at birth, the majority of children with congenital toxoplasmosis will have chorioretinitis, hearing loss, and/or developmental delays unless treated. Enzyme immunoassays are essential for the diagnosis of toxoplasmosis. Acute illness is confirmed by anti-*T. gondii* antigens IgM rise in the acute phase and a fourfold increase in IgG 3 to 4 weeks after the acute illness. A past infection, thus the possibility of reactivation, is established by the lifelong presence of specific IgG. A lymph node biopsy will show follicular hyperplasia and irregular clusters of tissue macrophages with eosinophilic cytoplasm. Granulomas and abscesses are not seen and hence it is important to differentiate this illness from acute cytomegalovirus or Epstein-Barr virus infections. Parasite DNA may also be detected by PCR techniques and may be useful in diagnosis in ocular disease. Pyrimethamine, sulfadiazine, and folinic acid is the treatment regimen of choice.

Rhinosporidiosis

Rhinosporidiosis is caused by *Rhinosporidium seeberi*, a protest belonging to the mesomycetozoea family of aquatic parasites. The disease is most prevalent in Southern India and Sri Lanka and causes "strawberry" lesions (pink lesion with whitish specs which are the chitinous walls of *Rhinosporidium* sporangia). In the nose, it produces painless mucosal papules that evolve into large and hyperplastic polypoidal masses, which characteristically bleed on touch. Other mucosal sites involved include the palpebral

conjunctiva, oropharynx, nasopharynx, maxillary antrum, larynx, external ear canal, and the parotid duct. Diagnosis is confirmed by histopathologic demonstration of the characteristic thick-walled giant sporangia containing up to 10,000 sporangiospores (86).

BONY LESIONS

Some of the more common idiopathic bone lesions of the head and neck are discussed in this section. Although their radiographic appearance may be similar (Figs. 17.8 and 17.9), these bony lesions can be differentiated by a thorough history and physical examination and radiographic evaluation.

Fibrous Dysplasia

Fibrous dysplasia (Table 17.7), a genetic but nonfamilial skeletal disorder wherein medullary bone is replaced by fibro-osseous tissue, manifests itself in three clinical forms: monostotic fibrous dysplasia, polyostotic fibrous dysplasia, and McCune-Albright syndrome. Monostotic fibrous dysplasia, the term applied when the disease is confined to one bone, accounts for 75% to 80% of all cases. Polyostotic fibrous dysplasia, which accounts for 20% to 25% of patients, is applied when two or more bones are involved. If polyostotic fibrous dysplasia is associated with abnormal skin pigmentation, precocious puberty, and other nonskeletal diseases, it is called McCune-Albright syndrome, which accounts for 20% to 25% of all polyostotic fibrous dysplasia patients.

Fibrous dysplasia occurs almost exclusively before age 30 years. Polyostotic fibrous dysplasia and McCune-Albright syndrome tend to occur in the first decade, and monostotic fibrous dysplasia usually manifests in the second or third decade. The disease is usually quiescent after puberty. Polyostotic fibrous dysplasia has a 3:1 female predominance. Monostotic fibrous dysplasia occurs with equal frequency in both sexes. The cause of the disease has been localized to postzygotic missense mutations in the *GNAS*1 gene, which is found on chromosome 20q13.2.

Most patients (90%) with fibrous dysplasia are asymptomatic. The most commonly affected bones are the ribs and femur for monostotic fibrous dysplasia and the femur and tibia for polyostotic fibrous dysplasia. About 25% of patients with fibrous dysplasia have head and neck involvement. The ethmoid, sphenoid, frontal, maxillary, and temporal bones are the most commonly affected. Head and neck symptoms include sinusitis, proptosis, diplopia, compression of the cranial nerves in foramina, facial pain, facial asymmetry, headache, and hearing loss.

The typical radiographic finding is an expanded osseous lesion with a poorly defined margin covered by an eggshell-thin cortex. Fibrous dysplasia also may appear radiographically as a pagetoid lesion or sclerotic lesion. When the paranasal sinuses are involved, radiographic studies show a calcified, thick, enlarged sinus margin and a ground-glass appearance of the mass inside the sinus.

Histologically, the fibrous dysplasia lesion reveals normal marrow-space bone replaced by irregular spindle-shaped mesenchymal cells. The mesenchymal cells form whorled patterns, and the bony trabeculae are poorly developed. One differentiating feature of fibrous dysplasia is the lack of "osteoblastic rimming," in which osteoblasts rim the fibro-osseous tissue.

The differential diagnosis for fibrous dysplasia often depends on the location and radiographic characteristic of the lesion. Although the fibrous dysplasia lesion may appear pagetoid radiographically, it can easily be differentiated clinically. When located along the sphenoid ridge, it may look radiographically like a meningioma. Fibrous dysplasia also may be difficult to differentiate from osteomyelitis, and the two conditions may coexist. Osteosarcoma must always be considered, as 1 in 200 cases undergo malignant degeneration. Biopsy should be performed if

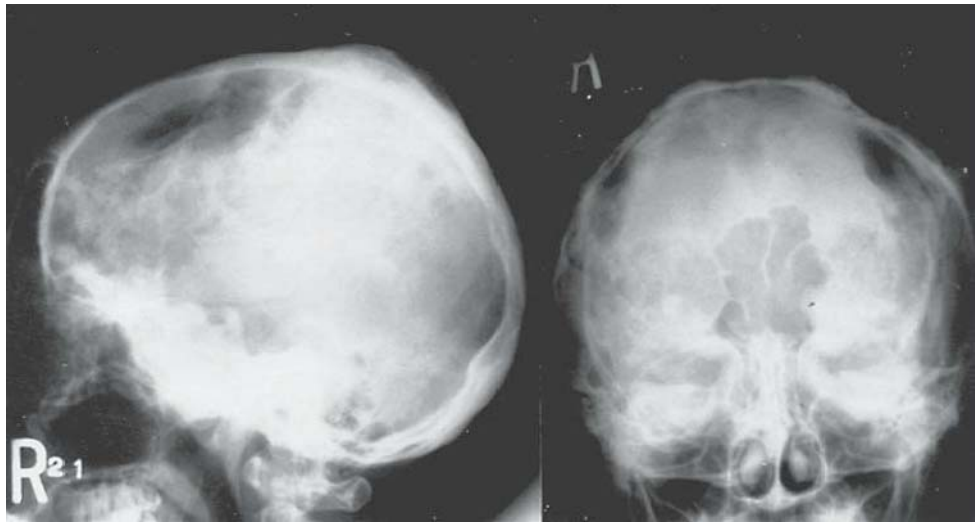

Figure 17.8 Fibrous dysplasia.

Figure 17.9 Paget disease. Note the pattern of thickened bone surrounding lucent bone.

the diagnosis is in doubt or if malignant degeneration is suspected. Surgical treatment for decompression of cranial nerves (typically the optic, cochleovestibular, or facial nerves) helps restore function but should not be performed prophylactically because of the risk of iatrogenic injury. Surgical curettage can help with diplopia and relieve sinus obstruction, although with this procedure, recurrence rates reach 20% to 30%. In recent years, refinements in surgical instrumentation and craniofacial surgical techniques have made more aggressive nondisabling procedures possible. Additionally, bisphosphonates may reduce the bony pain and risk of fractures (87).

Ossifying Fibroma

Ossifying fibroma is similar to fibrous dysplasia, but its onset, on average, is 10 years later. Its radiographic appearance is homogeneously dense in head and neck locations, similar to the appearance of fibrous dysplasia. The ossifying fibroma is usually more discrete. Histologically, it resembles fibrous dysplasia, but osteoblastic rimming is present. Treatment consists of excision, and recurrence is rare.

Paget Disease

The demographics and clinical manifestations of Paget disease (osteitis deformans) differ from those of fibrous dysplasia (Table 17.7). Paget disease rarely occurs before age 40 and most often occurs between ages 55 and 70. Most patients (85%) have polyostotic disease, and the lumbosacral region is the area most frequently involved. Patients with Paget disease are often asymptomatic but are more commonly symptomatic than are those with fibrous dysplasia. The classic symptoms are enlarging skull, dorsal kyphosis, and bowing of the legs. The most common symptom is bone pain. Other symptoms that occur as complications of the disease include spinal root compression, normal-pressure hydrocephalus, and repeated fractures with nonunion. Increased bone metabolism results in heightened vascularity of bone that has been reported to cause vascular steal syndrome and high output heart failure.

The classic radiographic findings of Paget disease follow the underlying histologic process. Initially, a lytic phase is associated with increased osteoclastic activity with replacement with vascular stroma, followed by a mixed phase, with increased osteoblastic activity in addition to the osteoclastic activity, resulting in a mosaic pattern of bone. The metabolic activity of the disease produces the typical "cotton wool" appearance on the radiograph. During the final phase, the osteoblastic activity is preeminent, and the radiographic picture becomes one of sclerosis. Calcium and parathyroid hormone levels may be elevated secondary to the increased bone turnover but are usually normal. Patients with Paget disease often have elevated alkaline phosphatase levels secondary to increased osteoblastic activity and increased urinary hydroxyproline levels secondary to increased osteoclastic activity. Recently, several

TABLE 17.7 FIBROUS DYSPLASIA COMPARED WITH PAGET DISEASE

Characteristic	Fibrous Dysplasia	Paget Disease
Age	≤30 y	≥40 y
Presentation	Monostotic	Polyostotic
Most commonly	Ribs, femur	Lumbar sacrum, affected bones
Most commonly	Maxilla	Skull affected, head and neck region
Treatment	Curettage	Bisphosphonates

studies suggest different markers to evaluate for rate of bone formation with bone-specific alkaline phosphatase or procollagen type 1N-terminal propeptide and bone resorption N-telopeptide (NTx). NTx is a sensitive way to assess for response to antiresorptive therapy (88).

In the head and neck, Paget disease occurs more commonly in the skull than in the face, as seen in fibrous dysplasia. The skull is the third most frequently involved bone. In the skull, lesions are typically lytic (i.e., osteoporosis circumscripta) and only slowly progress to the mixed phase. Paget disease of the jaw rarely occurs before age 40 and is usually bilateral. In contrast, fibrous dysplasia is usually unilateral and is rare after age 30.

Hearing loss is a common complaint by patients with Paget disease. This hearing loss includes a high-frequency sensorineural component and a low-frequency conductive component. The pathogenesis of the hearing loss has not been resolved (87).

The differential diagnosis for Paget disease includes fibrous dysplasia, osteomyelitis (which can coexist with Paget disease), osteitis fibrosa from primary hyperparathyroidism, and osteosarcoma. Like fibrous dysplasia, Paget disease can undergo malignant transformation. Approximately 5% of cases degenerate to an osteosarcoma, with the 5-year survival rate lower than that of other osteosarcomas. More rarely, Paget disease degenerates to giant cell tumor, which typically involves the skull and is less aggressive than other giant cell tumors, which rarely involve the skull and are seen almost exclusively in the long bones.

Usually the clinical and radiographic picture is classic, but a biopsy may help if diagnosis is in doubt. The patient with Paget disease also is at risk of serious sequelae developing, including hypercalcemia, polycythemia, neurologic compression, malignant transformation, and congestive heart failure. These patients need close follow-up. Medical treatment becomes necessary with impending hypercalcemia, repeated fractures and nonunion, compression of nerves, and intractable bone pain.

Calcitonin has been widely used; however, due to waning efficacy, absence of durable remission, and availability of better therapeutic options, it is currently used in rare circumstances. It decreases bone turnover and alkaline phosphatase levels, urinary hydroxyproline, and the risk for heart failure. In the last decade, bisphosphonates were developed. They are potent inhibitors of bone resorption and showed sustained clinical remission. These drugs have become the mainstay therapeutic option in Paget disease. Disodium etidronate was the first bisphosphonate studied, however, due to its negative effect on bone mineralization it was soon replaced by newer and better aminobisphosphonates (alendronate, pamidronate, risedronate, ibandronate, and zoledronic acid). This newer generation of bisphosphonates reflects a trend toward more potent suppression of bone resorption without impaired mineralization (89). All the bisphosphonates are generally well tolerated. Occasionally, they may cause flu-like symptoms and gastrointestinal distress. Rarely, and mostly with IV therapy for malignancy-associated bone metastasis, osteonecrosis of the jaw has been reported (90).

AMYLOIDOSIS

Amyloidosis is considered a rare disease, but autopsy studies suggest a higher incidence of subclinical disease than previously thought. In 1854, the term *amyloidosis* was coined by Virchow, who was describing a starch-like substance in a patient who died of multiorgan failure. Amyloidosis is characterized by the deposition of extracellular fibrillar proteins in various tissues. It manifests in several different forms: primary systemic, secondary systemic, localized, myeloma associated, dialysis associated, senile, and hereditary-familial amyloidosis. However, amyloidosis is extremely rare in the pediatric age group.

Of the two forms of amyloidosis, the AL amyloidosis (formerly primary systemic), which predominantly affects mesenchymal tissues (e.g., heart, tongue, and gastrointestinal tract) and AA amyloidosis (formerly secondary systemic amyloidosis), which is associated with chronic inflammatory destructive diseases such as tuberculosis, RA, juvenile RA, spondyloarthritis, autoinflammatory syndromes, and osteomyelitis. AA amyloidosis primarily affects the kidneys, adrenals, liver, or spleen and occurs after 10 to 20 years of inflammatory disease. Although amyloidosis develops in only 12% of patients, myeloma-associated amyloidosis is the second most common form. This form is deposited primarily in mesenchymal tissues. Localized amyloid may be primary or secondary, but it is limited to one site in the body and occurs in several neurodegenerative diseases such as Alzheimer disease, Parkinson disease, and Huntington chorea.

Although the mechanism of deposition is different, all fibrils in amyloidosis are of β-pleated sheet conformation. With light microscopy, all forms of amyloid are identical. Chemical analysis reveals that primary amyloid and myeloma-associated amyloid are composed of light-chain immunoglobulins (AL); this disease is a plasma cell dyscrasia. AL amyloidosis results from deposition of protein fragments that have been generated by aberrant proteolytic cleavage of normal Ig. Secondary amyloid is composed of amyloid protein A (AA). AA amyloidosis is the result of overproduction and deposition of serum amyloid A protein. Localized and familial amyloid may be composed of several different types of protein; the vast majority of familial amyloidosis is caused by deposition of transthyretin (TTR) variants. The dialysis-associated protein is β_2-macroglobulin. Nephrotic syndrome is the most common manifestation of systemic amyloidosis, either alone or with other organ system involvement, particularly restrictive myocardiopathy, hepatomegaly, peripheral neuropathy, and macroglossia. Ecchymosis due to capillary wall infiltration, bleeding due to factor X deficiency, carpal tunnel syndrome, arthropathy, lymphadenopathy, and gastrointestinal dysmotility are

all seen in systemic disease. Cardiac evaluation provides important clues in the diagnosis of systemic amyloidosis. In cases with cardiac amyloid infiltration it is common to observe a pattern of low QRS voltage on electrocardiogram (91). Echocardiographic features of amyloidosis include nondilated ventricles with concentric left ventricular thickening and increased echogenicity of the myocardium with a "granular sparkling" (92). Cardiac MRI is able to demonstrate myocardial late gadolinium enhancement with global and subendocardial localization and correlates with classical histologic changes observed in cardiac amyloidosis (93). The diagnosis of amyloid is established by biopsy, which is characterized by extracellular proteins that are green and birefringent under polarized light after staining with Congo red. Reversibility of the birefringence with potassium permanganate implies secondary amyloid. Crystal violet also is used to stain for amyloid. Biopsy for systemic amyloidosis is often accomplished by needle aspiration of abdominal fat, although biopsies of the tongue, minor salivary glands, and buccal mucosa have all been advocated (94). Diagnosis of the myeloma-associated form is diagnosed based on findings of plasma cells in bone marrow biopsies and monoclonal Ig light chains on plasma and urine electrophoresis.

Generalized amyloid has a worse prognosis than localized amyloid. As a result, these patients must be evaluated for generalized disease by a rectal biopsy or a fine-needle aspiration of the anterior abdominal wall fat. Eighty to ninety percent of patients with generalized amyloid show positive results with these tests.

Amyloid may deposit in several sites in the head and neck. The tongue is the most commonly involved area. Of those with AL amyloidosis, 50% have lingual involvement, but macroglossia is present in only 5% of patients, although it is considered pathognomonic. The orbit is another common site of deposition for localized amyloid in the head and neck. Typically, it is seen as a painless mass in the superior orbit. The true vocal cord is the most common site of deposition in the respiratory tract, although the supraglottis, subglottis, trachea, and bronchial tree also may be involved. In the larynx, the typical firm gray, red, or yellow deposits are usually localized. The nodules tend to be diffuse in the subglottis. Surgical reduction of amyloid lesions is the treatment of choice, and multiple procedures over a number of years may be required (95). Laryngeal amyloidosis tissue is relatively fragile and bleeds readily if traumatized. Anesthetists should be cautious when intubating patients with laryngeal amyloid involvement. Otologic manifestations of the disease are extremely rare and involve the external auditory canal and concha. Other head and neck sites of deposition reported include the parotid gland, oral and pharyngeal mucosa, minor salivary glands, the paranasal sinuses, cervical lymph nodes, the nasopharynx, and the skin. Treatment for amyloidosis comes in two parts, direct treatment of the underlying disease, if possible, and supportive treatment for the involved organs. AL is the most serious among the amyloid disorders with 18 to 24 months survival. Treatment with melphalan and autologous stem cell transplant extends the survival to 40 months (96). Treatment of AA amyloidosis is directed towards controlling the inflammatory disease process.

HIGHLIGHTS

- Rheumatologic diseases result from immunologic or autoimmune reactions.
- The tissue distribution of the inflammatory response, the pattern of organ involvement, and the presence of specific autoantibodies are the factors that differentiate one systemic autoimmune disease from another.
- Mucocutaneous and musculoskeletal involvement are the most common manifestations of SLE.
- Sudden unexplained onset of erythema and pain over the cartilages of the nose or ear suggests a diagnosis of polychondritis.
- It is possible that a significant overlap in the clinical presentation of the systemic autoimmune diseases exists, and if one patient exhibits distinct clinical characteristics of several of these diseases, the diagnosis of overlap syndrome or undifferentiated connective tissue disorders should be considered.
- LCH is the preferred term for the collection of disorders of proliferation of mononuclear phagocytic cells previously known as histiocytosis X.
- Sarcoidosis, characterized by noncaseating granulomas, most often involves the lungs and intrathoracic nodes; the cervical nodes are often involved when sarcoid appears in the head and neck.
- Cervical lymphadenitis, frequently involving the posterior triangles, is the most common head and neck manifestation of tuberculosis
- Although radiographically similar, bony lesions of the skull can be differentiated by their most common site of involvement and the patient demographics of those involved.

18 Geriatric Otolaryngology

David E. Eibling *Sarah H. Kagan*

Health care in our aging society is widely acknowledged as the force substantially altering current and future health needs, demand for services, and provision of primary and specialty care. Otolaryngologists, as specialists best prepared to treat senescent functional sensory loss and many age-related diseases and syndromes including dysphagia and malignancies of the head and neck, hold a unique role in provision of specialty care for older adults. Addressing health care needs of an aging society through provision of general otolaryngology and specialized otology, rhinology, and laryngology care, as well as head and neck surgery, requires knowledge of several specialized topics in aging and geriatrics. This chapter reviews central concepts relevant to an aging society. It then proceeds to detail aspects of clinical care for older adults relevant to the practice of otolaryngology as it relates to the future of health care. This discussion includes consideration of geriatric competence for the generalist and specialist otolaryngologist. The chapter concludes with consideration of the subspecialty of geriatric otolaryngology in health care for our aging society.

CONCEPTS IN AGING

Terms and Definitions

Language used to define and discuss issues of aging and health care for older Americans is often diverse and difficult to understand. Even terms of reference to older Americans themselves are somewhat controversial. Current conventions acknowledge the slightly pejorative connotation of the grammatically incorrect appellation elderly as a noun. The only accepted use of *elderly* is as an adjective; however, *older* is preferred in America and across most international scholarly literature in aging. While American scholars and clinicians often say "*older adults*," those in the European Union may prefer "*older people*." Interestingly, older adults themselves rank "elderly" among the most negative terms of reference (1). Words and phrases like "senior" or "50+" may be preferable to older adults, especially combined with individually and generationally expressed forms of address that avoid diminutives and informality. *Gerontology* is the name of the discipline that studies aging, health, and function from biologic, psychological, and social perspectives. *Senescence* refers to the process of aging and generally refers to cellular processes. Chronologic age is often subdivided into three categories. The *young-old* are ages 65 to 75. The *old* are generally considered aged 75 to 85. The *old-old*—or alternatively, *oldest old*—are those individuals aged over 85 and are currently the fastest-growing demographic (2). *Centenarians*—those over 100 years—and *supercentenarians*—those aged 110 years or older—while few in number are extensively studied to better understand extreme longevity (3). *Geriatric* is both the term used to define the biomedical study of age-related disease, dysfunction, and disability as well as being the name of the medical specialty of caring for older adults (4). Use of the word geriatric also delimits the subspecialty within other medical disciplines dedicated to care of older adults and to that within other professional groups. Examples of this use of term include geriatric otolaryngology, geriatric nursing, and geriatric social work.

Demographics and Disability

Emphasis on aging demographics and implications for health care are now commonplace in health care literature. Proportional change in the number of older Americans draws most attention. The current projection is that one in five Americans are expected to be aged 65 and older by 2030 (2,5). In some regions, the percentage of older Americans may rise to one in four or more. Significant

growth in the old-old, those individuals aged 85 and over, compounds this demographic shift (2). Current trends in population aging are the result of improved disease prevention and control and of extended longevity (2). Improved health status and declining disability in late life are also apparent (6).

Two concepts, existing in balance, explain health and social care burdens in an aging society. *Compression of morbidity*, classically defined by Fries (7), is the possibility of compressing illness and functional loss as close as possible to the time of death. The *elder dependency ratio* measures the number of older people against working adults. The elder dependency ratio, like the total dependency ratio that includes dependent children, evaluates care needs at a population level. These population measures are critical to understanding health care needs and projecting necessary services in any society.

Compression of morbidity, once only a concept yet to be realized within our population, is a current reality. Cutler and Landrum (6) offer current analyses reflecting significantly improved health and declining disability of our aging population overall. Notably for otolaryngology, Cutler and Landrum (6) suggest that sensory impairment is declining as elder health status is improving. Nonetheless, they also show stable use of nursing homes, implying potential persistence of unaddressed disability in the old-old. Cai and Lubitz (8) show older Americans are indeed increasingly experiencing compression of morbidity and disability in the time before death. However, in more discrete analyses, differential patterns of functional disability that signal commensurate health and social care needs remain a reality within the aged population.

Concerns about elder dependency ratios persist despite gains made in limiting disability and extending life (9). Some of these concerns lie in the accuracy of projections. Tuljapurkar et al. (9) suggest elder dependency ratios are in fact underestimated in most developed nations including the United States. Thus, in comparing research reported from different disciplines, some debate over projections of morbidity and consequent disability exists and warrants continued analysis to draw clinically relevant conclusions. While overall health status of older Americans is improving, dependency and specific forms of disability continue to drive improved health care education and workforce recruitment to address these needs in our aging population (5)

AGING, DISEASE, AND DISABILITY

Much science investigates interrelationships among aging, disease, and disability (10–14). However, these entities and their interactive and correlative effects in health and function remain incompletely understood, particularly in translating basic science into clinical contexts. *Frailty* is the state of declining functional reserve in which response to stressors is diminished, resulting in proportionally more severe sequelae and limited recovery after an insult (14). Fundamentally, study of processes like senescence and inflammation shed increasing light on frailty as a phenomenon of function understood now in physiologic dimensions, differentially expressed in late life (15,16). *Epigenetics* is the study of both heritable and nonheritable genetic expression and cellular transcription potential that is generally stable but may be modified by interactions with physiologic, pathologic, and environmental factors over a lifetime (17,18). Rising interest in epigenetics complements growing evidence in frailty (19). Evidence in epigenetics increasingly elucidates critical aspects of age-related diseases like dementia and cancer (18,20). Epigenetics may eventually clarify the triad of disability, frailty, and comorbidity outlined by leading frailty researcher Fried et al. (11).

Disability, frailty, and comorbidity are almost certainly causally related, manifesting in overlapping and difficult-to-distinguish patterns in late life (11). As molecularly mediated understandings of frailty and epigenetics frame translational science of aging and disease, investigation of frailty, age-related disease, and functional disability increasingly delimit related aspects of clinical geriatrics. Fried et al. (11) highlighted interchangeable use of these three terms, proceeding to outline overlapping prevalence and intercurrent sequelae. Comorbidity—diagnosis of two or more acute or chronic diseases—is highly prevalent in the old-old. The old-old bear proportionally more disability, presence of physical or mental impairment, than younger counterparts do. Both comorbidity and disability are commonly present in the case of clinical frailty. Accruing evidence continues to disentangle the clinical manifestations and consequences of these entities in prognosis, care needs, and health care costs (15,21–26).

Age-related disease and geriatric syndromes commonly coexist and may increase as frailty escalates (14). Frailty likely mediates age-related disease though exact mechanisms, beyond epigenetic influences and possible inflammatory processes, remain relatively obscure (18). Geriatric syndromes, unlike diseases with identifiable pathology at hand, are more complex. A geriatric syndrome, such as delirium, falls, or incontinence, manifests in a singularly identifiable presentation (27). However, manifold etiologic factors and interacting pathogenesis are at hand in any single syndrome (27). Unlike disease, there is not an authoritative and comprehensive list of geriatric syndromes. Some like sarcopenia and frailty draw debate and remain controversial. Other syndromes like delirium, falls, incontinence, malnutrition, or geriatric failure-to-thrive are more widely accepted.

Age-related disease and geriatric syndromes may interact, creating risk for complications and increasing care needs (14,28,29). A classic example exists in the older person with dementia who is then at greater risk for delirium. Once delirium emerges, this older person

may have a more complicated presentation and less predictable recovery (30). Both presentation—which is often atypical—and recovery may risk excess disability and poor outcomes (11,27,31). *Atypical presentation* describes unexpected signs of illness—such as delirium instead of fever as the presenting sign of pneumonia occurring in an older adult—that often conflict with typical signs and symptoms in diagnosis for a younger adult (31). Many authors contend that frailty is the element of declining functional reserve that undergirds age-related disease and geriatric syndromes (11,14,15,27). Others argue that frailty itself is a clinically identifiable geriatric syndrome (10,23). As biologic evidence accrues, the import of relationships between and among frailty, age-related disease, and geriatric syndromes for clinical medicine is clear. These interconnections require parallel investigation of prevention, treatment, and outcomes in the context of medical, surgical, and rehabilitative treatment (22,24,32–34).

CLINICAL CARE OF OLDER ADULTS

Geriatric competence optimizes care of older adults across specialties and settings (5,29,31,35). Specifically, geriatric competence limits risk of errors in high-risk settings and in hand-offs and transitions in care (31). Otolaryngologists of the 21st century will need geriatric competence to optimize the discipline's contribution to our aging society and to ensure best practices and outcomes for individual patients. Competence implies the possession of specific skill sets and a working knowledge of critical concepts, as well as understandings of current and future implications of an aging society.

Otolaryngologists are specialists in the diagnosis and treatment of disabling sensory and functional impairments, including presbycusis, presbystasis, presbynosmia, presbyphonia, and dysphagia (36). Such impairments beget often debilitating limitations in daily function and quality of life (6,36). Additionally, otolaryngologists lead surgical and interdisciplinary treatment of head and neck cancer. Along with diagnosis and treatment of other otolaryngologic conditions seen across the life span, otolaryngology residency training equips otolaryngologists with the knowledge and skill necessary to manage and collaborate in optimal interdisciplinary care of older adults. However, in the process of that care, otolaryngologists confront geriatric concerns that risk convoluted processes of care and poor clinical outcomes. Frequently, matters of atypical presentation intersect with comorbidities and geriatric syndromes to generate resultant questions of frailty, functional reserve, and rehabilitative potential. These geriatric concerns drive needs for specific knowledge regarding care of older adults. Conversely, such concerns also draw into question anecdotal reliance on a general sense of older adult patient outcomes, especially the false confidence of "I take care of older people and they do OK."

Possession of specific geriatric competence is vital to enhancing the domains of assessment, decision making, complications, and care in advanced, life-limiting disease. Assessment of older adults, given inherent complexity of frailty with comorbid disease and conditions along with geriatric syndromes, is among the most active research topics in clinical geriatrics (33,37,38). Nonetheless, many recommended protocols require extensive training and time unsuited to most specialist practices. Treatment decision making coalesces concerns about health care for the individual juxtaposed against comparative effectiveness and outcomes. Increasing evidence suggests that geriatric focused assessment alters decision making (32,39–41). Emerging understanding of links between geriatric assessment and decisions that employ assessment data potentially improves clinical management, resulting in improved patient outcomes and reduced postoperative complications (32,37,40).

Specific assessment, complex decision making, and risk of complications are all heightened in the older adults with advanced, life-limiting diseases such as dementia, cancer, and heart failure. The contributions of otolaryngology are particularly valuable to these individuals and their families. For many older adults diagnosed with advanced, life-limiting diseases, the presence of sensory and functional impairments makes daily life limited and quality painfully circumscribed. Diagnosis and treatment of these impairments fall precisely within the practice domain of otolaryngology. Consequently, otolaryngologists can markedly improve quality of life for such individuals, as consultants to primary treatment teams in community-based and institutional long-term care.

Geriatric Assessment

Geriatric assessment is the foundation for medical and interdisciplinary care of older adults. As such, specialized assessment targets the unique needs of older adults and accounts for manifestations of frailty with specific indicators (22,32,33,38). Accumulating evidence progressively reveals which frailty criteria are the most robust indicators in assessment (42), and clinical investigation highlights specific indicators and assessment protocols that are most clinically relevant (32,42). Classically, geriatric assessment protocols relied on a formal assessment technique called Comprehensive Geriatric Assessment (CGA). This global, multifocal, expert multidisciplinary process is time consuming and often requires hours to complete (43). Though CGA is clinically useful in identifying needs and risks, early work failed to establish its value in enhancing outcomes and comparative cost effectiveness definitively. As a result, there is no current standard to assess functional status and reserve of older patients facing serious, life-limiting diagnoses as well as standard interventions and procedures for primary and comorbid conditions (44).

Current CGA research is most robust in medical oncology. More recently, geriatric assessment is the focus of some investigations of frailty and outcomes in surgical and other medical specialties (33,37–39,44). Current investigations apply CGA principles in one of two ways. Investigations entail either a geriatric consultation team to complete assessments or application of specific assessment indicators that may be clinically feasible without geriatric expertise. Translation of consultation teams and targeted assessments to clinical practice remains limited. Interventions that rely on consultation teams are often not feasible for all but large medical centers with geriatric services or departments in place. Frailty phenotype indicators may be more useful. Makary et al. (32) and Robinson et al. (33) report findings that suggest clinical utility in the near future for easily assessed frailty parameters such as walking speed and weight loss. Conversely, Aparicio et al. (43) report a competing model, called Mini-Geriatric Assessment (MGA), that relies on assessment of geriatric syndromes and physiologic indicators. Both frailty phenotype indicators and MGA overcome some of the limitations of CGA and promise tangibly better clinical assessment. While evidence to shape future practice continues to accrue, critical clinical appraisal of frail-appearing patients and judicious use of geriatric consultation services augment current thorough otolaryngologic assessment and communication with primary care providers and referring physicians.

Substantial evidence exists confirming that utilizing assessment data that target frailty, comorbidity, and disability improves decision making and clinical outcomes (32,38,39,43,45). Yet, decision-making preferences among older adults are difficult to predict (46–48). Executing an *advance directive* is an important adjunct to improved decision making. Silveira et al. (49) suggest that those who have directives are more likely to receive the care they desire at end of life. Advance directives offer benefit in generating discussion among older individuals, their family members, and treating clinicians as much as in documenting wishes for the type and extent of care in serious illness and injury. Nevertheless, population prevalence of completed directives is generally low with higher numbers found in frail institutionalized older adults. Scalable solutions to improve adherence are, as yet, untested (49–51). Best practices in care of older adults, for specialists such as otolaryngologists and primary care providers alike, include eliciting patient and family preferences and recording advance directives in addition to geriatric assessment and communication between specialists and primary care providers (52–57).

Clinical Management

Effective clinical management of older patients, beyond the foundation of otolaryngologic and geriatric assessment and individualized decision making, requires a clear, goal-directed plan of care. Care of older patients is inherently interdisciplinary and implies cognizance of actual needs and potential complications (28,31,40). Inpatient care escalates risks, vulnerability, and opportunity for medical error and complications. Proactive prevention and treatment potentiate improved outcomes in medical management and perioperative care of older patients (31,58–61). Hospital regulatory, credentialing, and institutional quality edicts generally closely correlate with best geriatric practices. As a result, initiatives in patient safety, satisfaction, and centered care offer a familiar platform for improving care for older adults.

Patient safety for older adults implies discrete, nuanced risk related to confluent senescent and pathologic changes creating the potential for unexpected effects in the course of treatment. Polypharmacy, delirium risk, and fall-related injuries are among the most consequential potential events for any hospitalized older adult (27). These geriatric syndromes and their cascade of interconnections serve to illustrate how patient safety and geriatric best practices coincide.

Polypharmacy is the geriatric syndrome in which older adults are prescribed many drugs without due consideration of altered metabolism, drug–drug and drug–food interactions, and patient and family education (62). Senescent and pathologic changes in drug metabolism, distribution, and response complicate prescribing as does the presence of multiple prescribers (62). Careful medication management with consideration of alternate agents and pharmacist consultation offers the means to limit polypharmacy and adverse drug events when combined with routine and new prescription *medication reconciliation*.

Delirium, a syndrome of acute confusion with multiple etiologic factors, is prevalent among medically ill older adults and often complicates postoperative recovery (27,37,40). Undetected and hence unmanaged delirium poses a host of consequences from infection to death (63). While scant evidence and limited instruments limit composite screening for delirium risk, well-established research is revealing identifiable risk factors for delirium. Among the most common events likely to lead to delirium among older adults are presence of infection or other acute illness, metabolic derangement, and use of deliriogenic medications (63). Outcomes of care in delirium are improved by identifying risk, avoiding deliriogenic events when possible, detecting actual delirium early, deleting contributing drugs, correcting pathology when feasible, avoiding physical and chemical restraints, and employing early rehabilitation (63).

Falls and fall-related injuries result from manifold factors among community-dwelling, institutionalized, and hospitalized older adults, leading to substantial morbidity (58,64–66). Delirious patients are at increased risk of

falls given altered sensorium, impaired judgment, and the presence of acute illness. Detecting and treating delirium while providing rehabilitation to restore function may reduce or avoid fall risk. Preventing falls and resultant injury among older adults, regardless of setting, is difficult (66). Falls are prevalent among both community-dwelling and institutionalized older adults, and many intervention programs are relatively ineffective at preventing either falls or related injuries (64,66,67). Through ongoing research in presbystasis and other balance disorders, otolaryngology offers the potential to impact the epidemic of falls and consequent injuries among older adults (67,68).

Patient satisfaction receives ever more attention in our aging society. Measures of satisfaction drive a wide variety of initiatives from hospital incentive programs to hospital accreditation (55). Patient satisfaction is a monolithic icon of health care in the 21st century—gratefully accepted when reported measures are high and puzzled over when low. Care of older adults offers substantive anchors for analyzing and improving patient satisfaction. Assumptions about older adult and family needs and preferences along with ageism persist in health care and in society (69,70). Careful attention to older patients as they ask questions, express preferences, and request assistance in making decisions enhances opportunities to understand expectations and offer satisfaction (55). Avoiding ageist assumptions and actions by measuring functional status instead of delimiting care by chronologic age launches patient-centered decisions with realistic goals of care (44,55).

Communication, coordination, and collaboration facilitates care of older adults who have comorbid conditions and use health care services frequently. Clinicians who provide care to older adults find communication and collaboration improve both processes and outcomes of care (47,56,71). While older adult and family preferences for communication and involvement in decision making are difficult to predict, older adults almost certainly value care coordination (46,52). As a result, clear understandings of locally available geriatric and related specialists in addition to resources for community-based services for older people serve otolaryngologists well.

Identifying geriatric and related specialists and available resources in advance offers advantages in achieving collaborative, coordinated care for older adults. Academic medical centers are most likely to offer geriatric fellowship training and to have board-certified *geriatricians* on staff. *Geriatric nurse practitioners* often collaborate with geriatricians and may offer independent geriatric assessment in many settings. While geriatricians are primary care physicians, they also serve as effective specialist consultants for older adults who wish to remain in the care of a family physician but have complicated comorbidities and multiple geriatric syndromes. Geriatric and medical *social workers* function in many roles in community settings and in health care agencies serving older people. Geriatric social workers offer direct counseling and care coordination in addition to accessing community-based services for older people. *Area Agencies on Aging*, nongovernmental organizations located in each county in the United States (http://www.n4a.org/), are important gateways to these local resources. In addition to clinicians with specific expertise in care of older adults, colleagues such as physical and occupational therapists, speech language pathologists, and clinical nurse specialists possess particular skills useful in interdisciplinary care of older adults. For example, physical therapists assess gait and walking speed as part of their initial assessments, useful in determining frailty. Occupational therapists and speech language pathologists complete various aspects of cognitive assessment, proving further data important in frailty and rehabilitative potential. Clinical nurse specialists frequently direct inpatient safety and quality initiatives, providing programmatic information about delirium and falls prevention, for instance. In the absence of colleagues who can easily collaborate, a variety of useful handbooks, software, and applications are available for clinical guidance. Among the valuable is the American Geriatrics Society publication *Geriatrics at Your Fingertips*, a pocket-sized clinical guidebook updated each year and available in hard and soft copy (www.geriatricsatyourfingertips.org).

UNIQUE CONTRIBUTIONS OF OTOLARYNGOLOGY TO HEALTH CARE IN OUR AGING SOCIETY

Future contributions of otolaryngology to health care in our aging society entail balancing competence and specialization and building discipline specific science and models of care. Otolaryngology supplies essential specialization in alleviating functional and sensory impairments as well treating malignancies of the head and neck that otherwise would diminish longevity and quality in the lives of older Americans. Otolaryngologists require geriatric competence to realize these potential contributions fully. The need for otolaryngologic science and care of older adults will grow dramatically as our society continues to age and demographic and health projections are attained. Recent efforts to define opportunities and advance the unique contribution of otolaryngology claim two published research agendas developed in collaboration with the American Geriatrics Society (72,73), a textbook (74), and the nascent organization *The American Society of Geriatric Otolaryngology* (http://geriatricotolaryngology.org/). Continued work must fulfill the research agendas and help demarcate the subspecialty of geriatric otolaryngology with respect to the discipline of otolaryngology.

HIGHLIGHTS

- Changing demographics will lead to dramatic increases in numbers of older adults seeking care for otolaryngologic disorders.
- Possession of specific geriatric knowledge and skills will enable otolaryngologists to optimize the management of these older adults.
- Specific geriatric syndromes such as dementia, polypharmacy, and delirium will represent comorbidities for ever-increasing numbers of patients.
- Assessment of frailty can inform decision making for patients requiring surgical intervention.
- Attention to collaborative care paradigms, medication reconciliation, and reliable hand-offs have the potential to reduce medical error and adverse events.
- Shared decision making is enhanced when older patients complete an advance directive.
- Management of otolaryngologic disorders can dramatically improve quality of life for older adults.
- A goal of interdisciplinary geriatric care is *compression of morbidity* into the shortest period of time prior to death possible.

Headache and Facial Pain

19

Chase H. Miller *Alfredo S. Archilla*

Headache and facial pain are a common complaint in the otolaryngologist's office. Ninety percent of Americans experience headache in their lifetime. Referral is often made to determine if headache is sinus in origin, but in this chapter we see that sinogenic causes of headache and facial pain are infrequent. Primary headache disorders are much more common. Secondary causes of headache and facial pain comprise an extensive list. The otolaryngologist should be able to identify sinus pathology and diagnose and treat other common causes of headache.

Headache and facial pain can be grouped into primary, secondary, and other etiologies. Primary headaches include migraines, tension-type, cluster headaches, and chronic daily headaches (CDHs). Other primary headache disorders are beyond the scope of this chapter. Secondary headaches include those that have specific etiologies identified. This group can include trauma, vascular disorders, infections, neuralgias, neoplastic causes, and others. Facial pain can be divided into peripheral or central causes. Peripheral facial pain makes up the larger of the two and includes disorders of the head and neck that refer pain to this region. Examples include temporomandibular joint (TMJ) syndrome and various neuralgias. Central facial pain is secondary to intracranial pathology like neoplasms or vascular disorders. For simplicity, secondary headache and peripheral facial pain disorders have been grouped together in this chapter.

ANATOMY AND PHYSIOLOGY

The brain is not a sensory organ and therefore does not perceive pain, but the surrounding structures in the brain have nociceptive fibers that recognize pain. Intracranial structures that are pain sensitive include major venous sinuses, large cerebral vessels, upper cervical nerves, and cranial nerves (CNs) V, VII, IX, and X. The trigeminal nerve and its branches provide the majority of the somatosensory innervation to the head and face region. The trigeminal nerve is a mixed nerve containing sensory and motor components. The nerve exits the ventrolateral aspect of the pons and divides into three main branches from the Gasserian ganglion; the ophthalmic V1, maxillary V2, and mandibular V3 divisions. Disease in the anterior or middle cranial fossa refers to the scalp or face anterior to the coronal suture. Lesions of the posterior fossa structures refer to the back of the head and upper neck. The sphenoid sinus and sella refer to the vertex of the head. Pain from diffuse intracranial disease may cause both anterior and posterior head pain (1).

Electrical stimulation of the trigeminal ganglion causes a cascade of events that are thought to cause headache. These electrical impulses trigger neurogenic plasma extravasation. This initiates a sterile inflammatory response, which leads to pain. There is also an increase in extracerebral blood flow and release of calcitonin gene-related peptide (CGRP) and substance P (SP) (2). CGRP is the most potent peptide vasodilator and its release causes vasodilation, mast cell degranulation, and plasma extravasation. SP is involved in inflammatory processes and pain perception. Pain impulses from the dilation and inflammation are transmitted from the trigeminal nerve to the trigeminal nucleus caudalis (TNC) in the brain stem. Because activation of the TNC can result in referred migraine pain to the ophthalmic and maxillary regions, patients may present with pain or pressure felt around the eyes and sinuses. The superior salvatory nucleus (SSN) that carries cranial parasympathetic fibers lies in close proximity to the TNC. Stimulation of the TNC can cause parasympathetic symptoms of rhinorrhea, congestion, and lacrimation. A form of central sensitization takes place during migraine, which is evident by symptoms of allodynia. Allodynia is a common finding of pain from non-noxious stimuli like touching the scalp or hair (Fig. 19.1).

V_1- Ophthalmic n.
V_2- Maxillary n. and foramen rotundum
V_3- Mandibular n.
VII- Facial n.
N.C. - Nucleus Caudalis
L.G. - Lacrimal gland
SSN - Superior Salivatory Nucleus
TG - Trigeminal ganglion

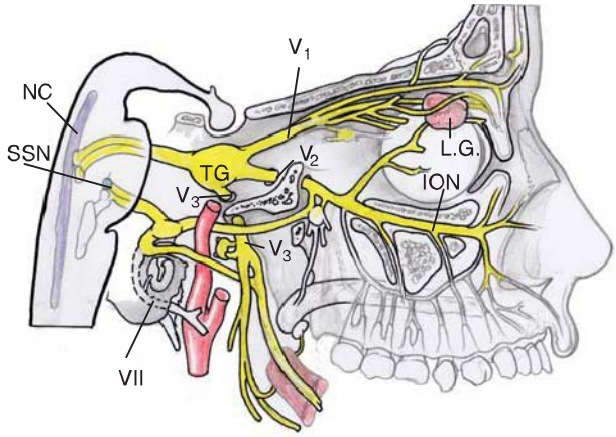

Figure 19.1 Trigeminal nerve. V1, ophthalmic nerve;V2, maxillary nerve and foramen rotundum; V3, mandibular nerve; VII, facial nerve; NC, nucleus caudalis; LG, lacrimal gland; SSN, superior salivatory nucleus; TG, trigeminal ganglion; ION, infraorbital nerve.

Depicted is the trigeminal nerve with its three major branches; ophthalmic, maxillary, and mandibular. The TNC is close to the superior salivary nucleus (SSN), which houses parasympathetic fibers. Activation of the TNC can cause reflex activation of the SSN giving rise to rhinorrhea, congestion, and lacrimation.

PRIMARY HEADACHES

Migraine is the most common primary headache and one of the leading causes of chronic illnesses and disability. Its prevalence is estimated at 18% of the US female population and 6% of the US male population (3). Two-thirds of women experience migraine before or during menses and these can worsen early in pregnancy. There is a significant decrease in episode frequency after menopause. About 70% of sufferers have a first-degree relative with migraines.

Migraine headaches are recurrent attacks lasting 4 to 72 hours. They are usually unilateral, pulsatile in nature, and of moderate to severe intensity. Attacks are often aggravated by physical activity. They are associated with nausea and/or photophobia and phonophobia. Most patients report at least one trigger of their migraine headaches. Common precipitating factors are emotional stress, hormonal changes in women, fasting, weather changes, sleep disturbances, odors, and alcohol (4).

Patients with migraine often have prodromal symptoms such as neck stiffness, euphoria, depression, fatigue, anorexia, food cravings, fluid retention, drowsiness, and enhanced alertness that begin 24 to 48 hours before the onset of headache. Fifteen to thirty percent of migraine sufferers have an aura preceding the pain. Auras are focal neurologic symptoms presenting as visual, motor, and sensory disturbances. Most auras develop slowly and may follow one another in succession starting with visual symptoms followed by sensory disturbances. Visual auras are most common and often present as zigzag figures near the point of fixation (fortification spectrum), moving geometric patterns, flashes of light, and scotomas. Sensory disturbances are frequently described as pins and needles affecting a small or large area of one side of the body and face. Numbness may also occur alone or in conjunction with other visual and sensory auras. Some patients experience a postdromal period where sudden head movements may precipitate short lasting pain in the location of the antecedent migraine headache. During this period, some patients feel tired and others have a sense of euphoria.

The diagnosis of migraine is clinical and relies on efficient history taking skills and detailed physical exam. The International Headache Society (IHS) divides migraines into two major subtypes; migraine without aura and migraine with aura. The latter is further subdivided into (i) typical aura with migraine headache, (ii) typical aura with nonmigraine headache, (iii) typical aura without headache, (iv) familial hemiplegic migraine, (v) sporadic hemiplegic migraine, (vi) basilar-type migraine. Each subtype has specific diagnostic criteria (Table 19.1). There are no diagnostic tests for migraine and neuroimaging is not necessary in most patients. A head computed tomography scan (CT) or magnetic resonance image (MRI) should be obtained if there are unexplained abnormal findings on neurologic examination, rapidly increasing frequency of headaches and atypical headaches that do not fulfill the strict diagnostic criteria established by the IHS.

Treatment for migraine headaches consists of acute headache resolution, avoidance of known triggers, and prevention of subsequent events. For mild to moderate nondisabling pain, oral nonsteriodal anti-inflammatory drugs (NSAIDs), acetaminophen, and aspirin are appropriate first choice agents. Caffeine may enhance the effect of the medications. Some patients do not respond to mild analgesics and need specific abortive therapies for acute migraine attacks. The triptans are serotonin 1b/1d agonists that inhibit the release of vasoactive peptides, promote vasoconstriction, and block pain pathways in the brainstem. They are used in outpatient situations because they are available in oral preparations, nasal sprays, and subcutaneous injections (Table 19.2).

Ergotamine and dihydroergotamine are other abortive therapies with similar pharmacology to the triptans, which are commonly used in emergency rooms and hospitalized patients. Ergots are serotonin 1b/d receptor and alpha-adrenergic receptor blockers that cause arterial and venous vasoconstriction. Dihydroergotamine is preferred over ergotamine for its safety profile. It is available for intravenous, intramuscular, subcutaneous, and intranasal use. Antiemetics are also used, alone or in combination with analgesics, for the treatment of acute migraine attacks. Commonly used agents include intravenous metoclopramide, intravenous and intramuscular chlorpromazine,

TABLE 19.1 DIAGNOSTIC CRITERIA FOR SELECTED MIGRAINE DISORDERS (5)

Migraine without aura

A. At least five attacks fulfilling criteria B–D
B. Headache attacks last 4–72 h (untreated or unsuccessfully treated)
C. Headache has at least two of the following characteristics:
   1. unilateral location
   2. pulsatile quality
   3. moderate-to-severe pain intensity
   4. aggravation by or causing avoidance of routine physical activity
D. During headache at least one of the following:
   1. nausea and/or vomiting
   2. photophobia and phonophobia
E. Not attributed to another disorder

Migraine with aura

1. Typical aura with migraine headache:
   A. At least two attacks fulfilling criteria B–D
   B. Aura consisting of at least one of the following, but no motor weakness:
      i. Fully reversible visual symptoms including positive features (e.g., flickering lights, spots,
      or lines) and/or negative features (e.g., loss of vision)
      ii. Fully reversible sensory symptoms including positive features (e.g., pins and needles) and/or negative features (e.g., numbness)
      iii. Fully reversible dysphasic speech disturbance
   C. At least two of the following:
      i. Homonymous visual symptoms and/or unilateral sensory symptoms
      ii. At least one aura symptom develops gradually over ≥5 min and/or different aura symptoms occur in succession over ≥5 min
   D. Headache fulfilling criteria B–D for *Migraine without aura*
   E. Not attributed to another disorder
2. Basilar-type migraine
   A. At least two attacks fulfilling criteria B–D
   B. Aura consisting of at least two of the following fully reversible symptoms, but no motor weakness:
      i. Dysarthria
      ii. Vertigo
      iii. Tinnitus
      iv. Hypacusia
      v. Diplopia
      vi. Visual symptoms simultaneously in both temporal and nasal fields of both eyes
      vii. Ataxia
      viii. Decreased level of consciousness
      ix. Simultaneously bilateral paresthesias
   C. At least one of the following:
      i. At least one aura symptom develops gradually over ≥5 min and/or different aura symptoms occur in succession over ≥5 min
      ii. Each aura symptom lasts ≥ or ≤60 mins

TABLE 19.2 AVAILABLE TRIPTANS AND MODE OF DELIVERY

1. Sumatriptan—subcutaneous injection, nasal, oral
2. Eletriptan—oral
3. Naratriptan—oral
4. Rizatriptan—oral
5. Zolmitriptan—nasal, oral
6. Almotriptan—oral
7. Frovatriptan—oral

and prochlorperazine. Abortive therapy is more effective if given early in the course of the headache. Patients should be treated with the safest, least expensive medications and advance to migraine-specific alternatives if the initial treatment fails.

Preventive treatment for migraine headache is indicated when headaches become recurrent (greater than four headaches per month), long lasting (>12 hours), and interfere with daily activities. Commonly used therapies include antihypertensives, antidepressants, anticonvulsants, herbal remedies, and acupuncture. Botulinum toxin injection to

trigger points (6) and surgical resection of trigger points like glabellar muscles and zygomaticotemporal branch of the trigeminal nerve are effective therapies for selected patients with moderate recurrent migraine that are difficult to manage with standard therapy (7).

TENSION-TYPE HEADACHE

Tension-type headache (TTH) is the most common type of primary headache in the general population. Epidemiologic studies have shown prevalence as high as 80% between 20- and 40-year-olds. Women are affected more than males. TTH tends to peak in the fourth decade with decreasing prevalence with increasing age. Sustained contraction of pericranial muscles was believed to be the cause of TTH, but studies have failed to prove a causative relationship. Terms like stress headache and muscle-contraction headache have been abandoned. The pathogenesis of TTH is unclear and is likely multifactorial. In the episodic form there is activation of peripheral nociceptors around blood vessels in muscles and tendon insertion resulting in increased muscle tenderness and headaches. In the chronic form, general pain sensitivity in the central nervous system is increased due to repetitive and sustained pericranial myofascial nociceptor activation (8).

TTH attacks are mild to moderate in intensity and are usually less debilitating than migraine attacks. The pain is constant, nonthrobbing, and localized to the occipitonuchal or bifrontal regions bilaterally. It is often described as tightness, fullness, or "viselike." Attacks are variable in duration, lasting from 30 minutes to 7 days. They are not associated with prodromal periods or auras. Nausea and vomiting are extremely uncommon. Muscle tenderness in the head, neck, and shoulders are usually associated with the headaches and its intensity will parallel that of the attack.

The IHS divides TTHs into an episodic and chronic form, each with specific diagnostic criteria (Table 19.3).

TABLE 19.3 INTERNATIONAL CLASSIFICATION OF HEADACHE DISORDERS 2ND EDITION DIAGNOSTIC CRITERIA FOR EPISODIC AND CHRONIC TTHs (5)

Episodic TTHs

1. Infrequent episodic TTH
   - A. At least 10 episodes occurring on <1 d/mo on average (<12 d/y) and fulfilling criteria B–D
   - B. Headache lasting from 30 min to 7 d
   - C. Headache has at least two of the following characteristics:
     1. bilateral location
     2. pressing/tightening (nonpulsating) quality
     3. mild or moderate intensity
     4. not aggravated by routine physical activity such as walking or climbingstairs
   - D. Both of the following:
     1. no nausea or vomiting
     2. no more than one of photophobia or phonophobia
   - E. Not attributed to another disorder
2. Frequent episodic TTH
   - A. At least 10 episodes occurring on ≥1, but ≤15 d/mo for at least 3 mo (>12 and <180 d/y) and fulfilling criteria B–D
   - B. Headache lasting from 30 min to 7 d
   - C. Headache has at least two of the following characteristics:
     1. bilateral location
     2. pressing/tightening (nonpulsating) quality
     3. mild or moderate intensity
     4. not aggravated by routine physical activity such as walking or climbingstairs
   - D. Both of the following:
     1. no nausea or vomiting
     2. no more than one of photophobia or phonophobia
   - E. Not attributed to another disorder

Chronic TTH

- A. Headache occurring on ≥15 d/mo on average for >3 mo (≥180 d/y) and fulfilling criteria B–D
- B. Headache lasts hours or may be continuous
- C. Headache has at least two of the following characteristics:
  1. bilateral location
  2. pressing/tightening (nonpulsating) quality
  3. mild or moderate intensity
  4. not aggravated by routine physical activity such as walking or climbing stairs
- D. Both of the following:
  1. no more than one of photophobia, phonophobia, or mild nausea
  2. neither moderate or severe nausea nor vomiting
- E. Not attributed to another disorder

Patients with episodic TTH have fewer than 15 attacks per month and do not cause a significant impact in quality of life or performance. They are further subdivided into infrequent episodic TTH (less than one episode a month) or frequent episodic TTH (more than one, but less than 15 attacks per month). Individuals with chronic subtypes have more than 15 attacks per month. Chronic forms evolve from episodic forms and are associated with greater economic and personal costs.

Although TTHs are the most common primary headache, patients do not routinely seek medical attention. The history will reveal the quality and duration of the attacks. Physical exam will reveal normal blood pressure, oxygen saturation, and no neurologic deficits. Tenderness may be elicited in the scalp or neck muscles. As for all primary headaches there are no diagnostic tests available for TTH. Imaging of the brain is indicated if the pain is sudden and severe in order to exclude other conditions such as subarachnoid hemorrhage. Stress has been reported to be the most common precipitant of TTHs. Anxiety, poor posture, and depression have also been associated with the development of attacks. Attacks are not precipitated by food, weather changes, or exposure to noxious odors.

The treatment of TTHs ranges from nonpharmacologic therapies to use of potent analgesics. Over-the-counter analgesics (NSAIDs, aspirin, and acetaminophen) are considered first-line therapies and have been shown to be beneficial in most cases (9). NSAID in combination with caffeine works better than NSAIDs alone, but carries a greater risk of side effects. Patients often try a number of medications before seeking medical attention. These medications should not be used more than 10 days a month to decrease the risk of medication overuse headaches. Preventive treatment of TTHs is indicated if the attacks are frequent, long lasting, or they have a significant impact on quality of life. Tricyclic antidepressants, serotonin–norepinephrine reuptake inhibitors, and anticonvulsant medications have been tried with variable success.

CLUSTER HEADACHES

Cluster headache is a type of primary headache that belongs to the trigeminal autonomic cephalagias, characterized by short-lasting attacks accompanied by autonomic symptoms. The pathophysiology of cluster headache is not completely understood. The most accepted theory is activation of the trigeminal–hypothalamic pathway causing central disinhibition of nociceptive and autonomic pathways. The prevalence of cluster headache is estimated to be less than 1% and affects mostly men. It is most common in the third decade of life. Most patients are chronic cigarette smokers and a small proportion have a history of recent head trauma.

Cluster headache attacks are short lasting (15 to 180 minutes) and may occur up to 8 times a day. Attacks may occur daily for several weeks followed by a period of remission. The headache is severe and frequently described as stabbing, sharp, and excruciating. The pain is unilateral in the orbital, supraorbital, or temporal regions. Auras, nausea, vomiting, and photophobia are rare. Sympathetic impairment and parasympathetic hyperactivity are found on the ipsilateral side. Autonomic symptoms, such as ptosis, myosis, lacrimation, sweating, rhinorrhea, and nasal congestion, are commonly described during an attack. In contrast to migraineurs, patients become agitated and restless, scream in pain and crawl on the floor in desperation, and hit their head against hard surfaces. Attacks may be evoked by alcohol consumption, nitroglycerin, and histamine. Other commonly described triggers include stress, extreme temperatures, glare, and sexual activity.

The diagnosis of cluster headaches does not require extensive laboratory testing or imaging. CT or MRI of the head is recommended for initial evaluation of patients with cluster headaches and when the exam reveals atypical features or neurologic deficits. The IHS published specific diagnostic criteria for cluster headaches and divides them into episodic, more than 1 month of remission, and chronic, less than 1 month of remission (Table 19.4).

As with other primary headaches, treatment of the attacks are divided into abortive and preventive. First-line therapies for the treatment of acute cluster headaches include 100% oxygen at 12 L/min via nonrebreather mask and/or subcutaneous sumatriptan. Other commonly used abortive medications include intranasal sumatriptan, intranasal and oral zolmitriptan, subcutaneous octreotide, and intranasal lidocaine. Preventive therapy is recommended at the onset of an attack in order to avoid future attacks over the expected cluster period. Verapamil 240 to 320 mg/day is the drug of choice for preventive therapy. Glucocorticoids, lithium, ergotamine, valproic acid, and topiramate are other pharmacologic therapies that have been used with mixed results. Surgical procedures directed at the trigeminal nerve are rarely employed and only recommended for attacks refractory to all available pharmacologic intervention. Gamma knife radiosurgery, nerve sectioning, radiofrequency thermoregulation, and deep brain stimulation have been described.

CHRONIC DAILY HEADACHES AND MEDICATION OVERUSE HEADACHE

CDHs are a common problem affecting 4% of the population. Headache clinic-based studies find 80% of patients have CDH (10). Most CDH sufferers have a primary headache disorder that has been transformed into a chronic form. Classification of CDH requires headache on 15 or more days per month. Classification is then further broken down by average daily headache duration (less than or greater than 4 hours). Workup requires determining if there is a secondary disorder underlying the frequent headaches. Patients in chronic pain often overuse medication, which can play a role in initiating or sustaining pain.

TABLE 19.4 INTERNATIONAL CLASSIFICATION OF HEADACHE DISORDERS 2ND EDITION DIAGNOSTIC CRITERIA FOR EPISODIC AND CHRONIC CLUSTER HEADACHES (5)

Cluster headache diagnostic criteria:
- A. At least five attacks fulfilling criteria B–D
- B. Severe or very severe unilateral orbital, supraorbital, and/or temporal pain lasting 15–180 min if untreated
- C. Headache is accompanied by at least one of the following:
  1. ipsilateral conjunctival injection and/or lacrimation
  2. ipsilateral nasal congestion and/or rhinorrhea
  3. ipsilateral eyelid edema
  4. ipsilateral forehead and facial swelling
  5. ipsilateral meiosis and/or ptosis
  6. a sense of restlessness or agitation
- D. Attacks have a frequency from one every other day to 8 per day
- E. Not attributed to another disorder

1. Episodic cluster headache diagnostic criteria:
   - A. Attacks fulfilling criteria A–E for cluster headache
   - B. At least two cluster periods lasting 7–365 days and separated by pain-free remission of ≥1 mo
2. Chronic cluster headache diagnostic criteria:
   - A. Attacks fulfilling criteria A–E for cluster headache
   - B. Attacks recur over >1 y without remission periods or with remission periods lasting <1 mo

Medication overuse headaches have previously been known as rebound headache. Approximately 5% to 10% of headache sufferers have medication overuse headache. Medication overuse can exacerbate a primary headache disorder, interfere with effectiveness of preventive medications, or cause tolerance. This is a behavioral disorder and fulfills the criteria for physical dependency. Overuse medications include analgesics, opioids, ergotamine, and triptans. The International Headache Society Classification requires headache for 15 days per month with medication usage 3 months or greater.

Treatment of CDH can be difficult. Acute medications should be limited and prophylactic medications can be started realizing that they may not be effective until the abused medications have been removed. During the withdrawal of acute medication, patients may need psychological support. Encourage regular sleep, exercise, and meals. Patients may have severe exacerbations of their migraines during removal of the acute agents. Additional treatment called headache terminators may be needed to break the cycle of CDH (10,11).

SECONDARY HEADACHE AND FACIAL PAIN

Initial evaluation of the headache patient requires a careful history, physical and neurologic exam. A search should be made for certain "red flags" that increase the suspicion of a secondary headache disorder. Table 19.5 lists concerning findings that should be further evaluated.

In addition to the complete ENT exam further evaluation should include the retina (papilledema), cerebrovasculature (temporal arteries or carotid bruits), cervical paraspinal muscles, and TMJ. Red flag findings or positive findings on exam should be clarified with additional diagnostic tests if indicated. Neuroimaging should include preferably MRI, if available, or CT scan. A complete review of all secondary headache causes is beyond the scope of this chapter. Table 19.6 is a list of possible causes of secondary headaches. Following is a review of the more pertinent otolaryngology diagnoses.

SINOGENIC PAIN

True sinus causes of headache are uncommon. Sinogenic causes can include allergic rhinitis, acute rhinosinusitis, mucocele, mucosal contact headaches, or neoplasm. Other common nasal conditions like nasal polyps and mucus retention cysts rarely cause pain. Sinus headaches are most commonly a primary headache disorder. A study performed in 2002 questioned 100 consecutive patients responding to the symptom of sinus headache. Among them, 86% met criteria for

TABLE 19.5 SECONDARY HEADACHE RED FLAGS

- New onset severe headache/thunderclap headache
- Rapidly increasing headache frequency
- Headaches after trauma
- Headache with systemic symptoms of fever, chills, mental status changes
- Headache in immunocompromised individual
- New onset headache in age >50
- Focal neurologic signs
- Headaches associated with increases in ICP (cough, sneezing, valsalva)
- Headache awakening one from sleep

TABLE 19.6 SECONDARY CAUSES OF HEADACHE

Vascular: temporal arteritis, HTN, cavernous sinus thrombosis, cerebral aneurysm, AV malformation
Musculoskeletal: neck and shoulder muscle contraction, strain of extraocular or intraocular muscles, cervical spondylosis, temporomandibular arthritis
Infections: meningitis, encephalitis, brain abscess, sepsis, sinusitis, osteomyelitis, parotitis, mastoiditis, herpes zoster
Neoplasm: cerebral neoplasms, pheochromocytoma
Subdural hematoma
Cerebral hemorrhage/infarct
Pseudotumor cerebri
Normal pressure hydrocephalus
Post LP
Trauma
Dental: abscess, periodontitis, poorly fitting dentures
Neuralgia: sphenopalatine, glossopharyngeal, Sluder's, occipital
Eye: glaucoma
Metabolic: uremia, carbon monoxide inhalation, hypoxia, hypoglycemia
Endocrine: hypothyroidism
Drugs: alcohol, nitrates, histamine antagonists
Paget disease of the skull
Effort induced: exertional, cough induced, coital cephalagia
Emotional/psychiatric

migraine or probable migraine. Only 3% were diagnosed with rhinosinusitis (12). This can be confusing to the patient and the clinician especially because it is not unusual for migraine referred to the distribution of the trigeminal nerve to have parasympathetic symptoms of rhinorrhea, congestion, or lacrimation. Those patients who do have headache and facial pain from rhinosinusitis often have associated symptoms of nasal obstruction, hyposmia, or purulent nasal drainage. The American Academy of Otolaryngology Head and Neck Surgery includes headache as only a minor factor in the diagnosis of acute rhinosinusitis (Table 19.7). Facial pain alone does not constitute rhinosinusitis without another major factor.

TABLE 19.7 CRITERIA FOR DIAGNOSIS OF RHINOSINUSITIS—2 MAJOR OR 1 MAJOR AND 2 MINOR (13)

Major Factor	Minor Factors
Facial pain/pressure	**Headache**
Facial congestion/fullness	Fever (chronic)
Nasal obstruction/blockage	Halitosis
Nasal discharge/purulence/discolored postnasal drainage	Fatigue
Hyposmia/anosmia	Dental pain
Purulence in the nasal cavity on exam	Cough
Fever (acute rhinosinusitis only)	Ear pressure/pain/fullness

TABLE 19.8 HEADACHE ATTRIBUTED TO RHINOSINUSITIS (5)

Diagnostic criteria
A. Frontal headache accompanied by pain in one or more regions of the face, ears, or teeth and fulfilling criteria C and D
B. Clinical, nasal endoscopic, CT and/or MRI imaging and/or laboratory evidence of acute or acute-on-chronic rhinosinusitis
C. Headache and facial pain develop simultaneously with onset or acute exacerbation of rhinosinusitis
D. Headache and/or facial pain resolves within 7 d after remission or successful treatment of acute or acute-on-chronic rhinosinusitis

The IHS has specific criteria for headache due to rhinosinusitis. Diagnosis requires a history of associated symptoms and clinical evidence via examination or radiologic studies. Nasal endoscopy, CT, or MRI can be used to determine the presence of rhinosinusitis. The IHS classifies sinus headache as a secondary diagnosis as illustrated in Table 19.8.

Headache from paranasal sinus disease is characterized by deep, dull pain that may or may not pulsate. Typical referral patterns exist as recorded in Table 19.9. Based on the studies by Wolff most pain emanating from the sinuses is related to inflammation and engorgement of the turbinates, ostia, and nasal frontal ducts. Anatomical narrowing can create contact points between mucosal surfaces. These trigger points cause referred pain.

Other causes of headache include rhinitis, mucoceles, neoplasm, and contact points. Nasal mucoceles or neoplasms often reach a notable size before symptoms of obstruction of the ostia cause pain and symptoms. Nasal mucosal swelling and anatomical abnormalities like concha bullosa or septal deflections can cause contact points and theoretical pain. Release of SP can occur locally and centrally through the trigeminal pathways.

TABLE 19.9 HEADACHE AND FACIAL PAIN LOCATION IN ACUTE SINUSITIS (14)

Paranasal Sinus	Location of Pain
Frontal	Frontal region Vertex
Maxillary	Over the antral area Radiate to upper teeth Forehead
Ethmoid	Nasion Retro-orbit Radiate to temporal
Sphenoid	Occipital Vertex Frontal region Retro-orbit

Various studies have been performed to evaluate the validity of contact points between membranes as the cause of rhinogenic headache. Palpation of the contact point or injection of Xylocaine with 1:100,000 epinephrine to contact point during a headache has been tried. Jones has, however, found that 50% of these contact areas are on the side opposite the side of the pain (15). Case reports and series exist showing improvement in headache pain from 30% to 90% after surgical treatment of these areas. Treatment varies from turbinate reduction, septoplasty, to directed endoscopic ethmoidectomy. Long-term studies by Welge-Luessen have been performed with almost 10-year follow up revealing 65% improvement (16). No controlled or randomized studies have been performed to investigate the validity of surgical treatment.

NEUROPATHIC PAIN

Neuropathic pain is nerve-type pain affecting any CN with sensory division or sensory nerve in the head and neck. The most common nerves affected include the trigeminal nerve and cervical roots 1, 2, and 3. Common disorders include trigeminal, glossopharyngeal, or occipital neuralgia. Pain is described as electric shock, sharp, or burning. Triggers often include non-noxious stimuli like touching of the scalp. Causes can include inflammation, trauma, vascular compression due to tumors or bone projections as seen in Eagle syndrome.

TRIGEMINAL NEURALGIA

Trigeminal neuralgia is the most common cranial neuralgia. Pain is unilateral, brief, lancinating pain limited to the distribution of CN V. The maxillary and mandibular branches of CN V are most commonly affected. Typical triggers include washing, shaving, talking, or brushing teeth. Women are more commonly affected than men during the fifth to seventh decade. Workup should include MRI to rule out other diagnoses. Vessel compression is best visualized on magnetic resonance angiogram (MRA). Table 19.10 lists the differential diagnosis of trigeminal neuralgia.

TABLE 19.10 DIFFERENTIAL DIAGNOSIS OF TRIGEMINAL NEURALGIA

Multiple sclerosis
Basilar artery aneurysm
Arterial or venous compression
Tumor
Postherpetic neuralgia
Temporal arteritis
Temporomandibular syndrome

Treatment of trigeminal neuralgia is directed toward prophylactic treatment most commonly using the antiseizure medication carbamazepine. Other medications include gabapentin, baclofen, phenytoin, sodium valproate, and chlorphenesin. Surgical treatment is reserved for medical failures. Extracranial peripheral denervation involves treatment at trigger points, which can be temporary using local anesthetics or permanent using alcohol, freezing, and heating. Surgical radiofrequency ablation involves destruction of the Gasserian ganglion by radiologic guidance of a device inserted into the cheek and through the foramen ovale into the Gasserian ganglion. The usage of glycerol injection called glycerol trigeminal rhizotomy is effective but has a high recurrence rate. Microvascular decompression is utilized to treat vascular loop compression of the trigeminal nerve by suboccipital retromastoid craniectomy. Other procedures utilized include gamma knife radiosurgery and botulinum toxin injections (1,17,18).

GLOSSOPHARYNGEAL NEURALGIA

Glossopharyngeal neuralgia is an uncommon disorder involving CN IX. This was first described in 1910 by Weisenburg described as repetitive, brief attacks or lancinating pain located in the soft palate, base of tongue, tonsillar fossa, and ear. Older men are most commonly affected between ages 50 and 60. Episodic attacks are triggered by pressure in the tonsillar fossa or hyothyroid membrane. Symptoms can be provoked by swallowing, yawning, and sneezing. Rarely this disorder can be associated with syncope when vascular compression of the nerve results in dysfunction of the glossopharyngeal-vagus reflex arc with bradycardia or asystole (19). Workup requires MRI evaluation to rule out oropharyngeal malignancy, infection, or vascular compression. Treatment is similar to trigeminal neuralgia. Surgical options are reserved for medical failures and include CN section or microvascular decompression of CN IX.

Eagle syndrome is a variant of glossopharyngeal neuralgia where the styloid process or a calcified stylohyoid ligament compresses CN IX causing symptoms of referred otalgia. Pain tends to be more persistent and dull in character (17–19)

OCCIPITAL NEURALGIA

Occipital neuralgia is defined by paroxysmal stabbing pain in the distribution of the greater and lesser occipital nerve. This is to be distinguished from a deep, aching pain in the occiput arising from diseases of the posterior cranial fossa and skull base. Associated symptoms can include visual disturbances, dizziness, nausea, tinnitus, and scalp paresthesias. Diagnosis is made by relief of pain by a nerve block. Treatment includes heat, physical therapy, transcutaneous electrical nerve stimulation (TENS) units, nonsteriodal medications, baclofen, and carbamazepine. Local blocks with bupivacaine, steroids, and alcohol can be performed. In protracted cases, nerve section has been performed.

SLUDER SYNDROME

Sluder syndrome was originally described in 1908 as unilateral, burning pain involving the lateral side of the nose, eye, forehead, and temporal or mastoid regions. Autonomic symptoms include lacrimation, rhinorrhea, and injected conjunctiva. This syndrome is now classified as a cluster headache but it is a form of sphenopalatine neuralgia. The term is now used loosely. Septal spurs impinging on the lateral nasal wall have been described as causing neuralgia. Diagnosis is aided by application of anesthesia in the region of the sphenopalatine ganglion. Treatment includes application of cocaine to the mucosa overlying the ganglion, removal of septal spur, or ablation of the sphenopalatine ganglion (18,20).

HEADACHE ASSOCIATED WITH VASCULAR DISORDERS

Headache in vascular conditions presents acutely and with associated neurologic signs and symptoms. Headache can be an initial warning symptom and it is crucial to recognize its association with vascular disorders. Warning signs include rapid onset of headache unrelieved by usual analgesics, persists or worsens, and becomes associated with other neurologic signs. Table 19.11 lists vascular causes of headache.

SUBDURAL HEMATOMA

Subdural hematoma is the most common cause of severe headache with abrupt onset. The patient who presents to the emergency room with a severe first or worst headache needs to be taken seriously. Subdural hematoma is life threatening with 50% mortality rate. Headache and third nerve palsy may be an early warning sign of impending aneurysmal rupture. Associated symptoms include nuchal rigidity, photophobia, fever, loss of consciousness, diplopia, or seizures. Workup includes a noncontrast CT scan, and if this is negative, a lumbar puncture (LP) is performed looking for elevated pressure and red blood cells. Patients should be hospitalized where there are appropriate neurosurgical services (18,21).

TABLE 19.11 VASCULAR CAUSES OF HEADACHE

Ischemic stroke
TIA
Subarachnoid hemorrhage
Cerebral aneurysm
Arteriovenous malformation (AVM)
Cerebral venous sinus thrombosis
Dural AV fistula
Giant cell arteritis
Carotid or vertebral artery dissection

TEMPORAL ARTERITIS

Temporal arteritis occurs most commonly in women greater than 50 years of age. Headaches are moderate to severe with a variable presentation. Pain can be burning, sharp or throbbing, bilateral or unilateral, intermittent or continuous. Jaw claudication is highly characteristic occurring in 40% with rare tongue claudication in 4% (21). Temporal or occipital artery thickening and tenderness occurs in two-thirds of patients. The most dreaded symptom includes blindness in 30% of untreated patients. Associated symptoms include scalp sensitivity, polymyalgia, fatigue, low-grade fever. Diagnosis is made by elevated erythrocyte sedimentation rate (ESR) and c-reactive protein (CRP). Temporal artery biopsy reveals inflammation. Skip lesions can occur requiring long biopsy segments up to 5 cm to prevent false-negative results. Treatment includes high-dose prednisone 40 to 80 mg/day. Response is generally rapid in 24 to 48 hours but long-term steroids may be required to prevent visual loss (18).

CAROTIDYNIA AND CAROTID ARTERY DISSECTION

Classic findings of carotid artery dissection include sudden onset ipsilateral headache and/or neck pain with Horner syndrome. Head pain can refer to the ear or involve the ophthalmic division. Pain is often associated hours later with transient ischemic attack (TIA), stroke, or retinal ischemia. Arterial dissection can be seen on ultrasound, MRI/MRA, or angiography. Treatment involves early anticoagulation to avoid 15% mortality (18).

Carotidynia refers to radiating pain from inflammation of the carotid fascia to the jaw, face, ear, eye, or head. Pain is variable in its characteristic and duration. Pain is worsened by swallowing, sneezing, coughing, and neck motion. Other disorders should be ruled out including carotid dissection, aneurysm, and giant cell arteritis. Treatment includes NSAIDs (21).

HEADACHE ASSOCIATED WITH NONVASCULAR INTRACRANIAL DISORDERS

In this category of disorders, the otolaryngologist should be familiar with idiopathic intracranial hypertension otherwise known as pseudotumor cerebri or otitic hydrocephalus. Reduced CSF absorption is thought to cause a rise in intracranial pressure (ICP) and resultant symptoms. This entity is most common in obese females between the ages of 20 and 42. The headache is described as severe, daily, and pulsatile. Symptoms are made worst by cough, straining, or exertion. Papilledema is the hallmark of the disorder with elevated CSF pressure but otherwise normal

neurologic exam. Associated symptoms include tinnitus, visual changes, CN VI palsy, weight gain, endocrine abnormalities and predisposing mastoiditis or ear infection. Evaluation reveals normal MRI and contrast-enhanced CT scan with elevated CSF pressure on LP. The cornerstone of treatment includes weight loss, low salt diet, and diuretics including acetazolamide to reduce CSF production or furosemide. In chronic cases, surgical shunting or optic nerve sheath fenestration for decompression is performed.

HEADACHE OR FACIAL PAIN ASSOCIATED WITH CRANIOFACIAL OR CERVICAL DISORDERS

Cervicogenic headaches are relatively common secondary to cervical spine abnormalities. This term was first introduced in 1983 by Sjaostad et al. but is considered a controversial term. Women are more commonly affected than men and there is often a history of trauma. Headache is unilateral or bilateral localized to the occiput but can radiate to the frontal region. Pain is triggered by neck movement or palpation of trigger points. Pain is constant with episodes of throbbing. Associated symptoms include nausea, vomiting, photophobia, phonophobia, and blurred vision. On exam, tenderness over the suboccipital, C2, C3, or C4 regions with reduced range of motion is found. Cervical radiographs can reveal abnormalities on flexion–extension films, abnormal posture, and bone or joint pathology. Treatment includes physical therapy and NSAIDs. Nerve blocks can be diagnostic and therapeutic. Botulinum toxin injections have been used (23).

TEMPOROMANDIBULAR JOINT SYNDROME

TMJ syndrome is a collective term including intracapsular and myofascial pain disorders. Females between the ages of 20 and 40 are most commonly affected. The disorders are characterized by facial pain, otalgia, and headache. Organic causes are less common than myofacial pain disorder. Myofacial pain dysfunction is a muscular disorder that has a multifactorial origin including stress. Pain is diffuse and poorly localized. Early morning exacerbations are typical with dull, radiating pain. Pain is elicited on palpation of the joints. Treatment includes education of causes. A more comprehensive discussion of TMJ syndrome can be found in Chapter 54.

CONCLUSION

Headache and facial pain are commonly seen by the otolaryngologist. Primary headache disorders are much more common than headaches originating from the sinuses. History and physical exam are paramount to identifying underlying causes. MRI and CT scan are indicated based on identification of red flags including rapid onset, worsening headache, neurologic signs, associated fever, and history of trauma or headache awakening one from sleep. Secondary causes of headache including neuralgias, vascular disorders, cervical spine abnormalities, and TMJ syndrome should be recognized by the otolaryngologist. Many of these disorders are in the realm of treatment by the otolaryngologist.

HIGHLIGHTS

- Primary headache disorders are the most common cause of headache and facial pain.
- Pain sensitive intracranial structures include major venous sinuses, large cerebral vessels, upper cervical nerves, and CNs V, VII, IX, and X. The trigeminal nerve provides the majority of the innervation to the head and face region.
- Migraine headaches are the most common primary headache disorder lasting 4 to 72 hours. Diagnosis is made mainly by history. Associated symptoms include nausea, photophobia, and phonophobia. Most patients can identify at least one trigger. Auras are identified in 15% to 30% of migraine sufferers.
- Effective treatment for migraine includes acute headache resolution, avoidance of triggers, and preventions. Abortive treatments include analgesics, triptans, or ergotamine taken early in the course of the headache. Preventive treatment is indicated when headaches occur more than 4 per month, long acting greater than 12 hours, or interfere with daily activities.
- Secondary headache disorders are numerous. Red flags indicating further workup needed include rapid onset, rapid increasing frequency, history of trauma, systemic symptoms of fever, chills, change in mental status, age greater than 50, focal neurologic signs, headache upon awakening, or headache with signs of elevated ICP. MRI is the preferred study in most conditions.
- True sinus headaches are uncommon. Pain is usually deep, dull pain emanating from engorgement of the turbinates, sinus ostia, or nasofrontal ducts. Causes of sinogenic headache include rhinitis, acute rhinosinusitis, mucoceles, neoplasm, and contact points.
- The most common cause of neuropathic pain includes the trigeminal nerve and cervical roots 1, 2, and 3. Common disorders include trigeminal neuralgia, glossopharyngeal and occipital neuralgia. Trigeminal neuralgia is the most common cranial neuralgia involving most commonly women age 50 to 70.
- Vascular headaches present acutely and with associated neurologic signs. Subdural hematoma is the most common cause of severe, abrupt headache. Headache and third nerve palsy can be early signs of aneurysmal rupture.

20 Complementary and Alternative Medicine

Li-Xing Man *Nicholas C. Sorrel*

A landmark survey by Eisenberg et al. (1) in 1993 surprised the medical community by revealing that over one-third of Americans used unconventional therapies for health and well-being. Three-quarters of these individuals did not inform their physicians of this practice. In a follow-up study, Eisenberg et al. (2) found that the prevalence of unconventional therapy use increased from 33.8% in 1990 to 42.1% in 1997. The most recent data from the 2007 National Health Interview Survey (NHIS) show that 38.3% of American adults and 11.3% of children had used a complementary and alternative medicine (CAM) in the past year (3). Estimated expenditures on CAM increased 25.6% between 1997 and 2007, with 22.0 billion dollars spent on CAM products and 11.9 billion dollars spent on 354.2 million CAM practitioner visits annually (4).

CAM usage is similarly common in other countries. In 2004, an estimated 52% of the Australian population had used a CAM therapy in the last year (5). A 2005 survey by the Canadian government found that 71% of Canadians had used a natural product in their lifetime, with 38% of this group using them on a daily basis (6). In Germany, approximately 60% of adults had used a natural or alternative healing method in the preceding year (7).

The use of CAM therapies has increased over the past several decades, and trends indicate that utilization will continue to increase (5,8). This burgeoning interest in CAM treatments can be monitored in the popular press, in bookstores, and on the internet. Formal courses on CAM have been introduced into the medical school curriculum (9), and a number of peer-reviewed journals are dedicated to CAM topics. The U.S. Congress established the National Center for Complementary and Alternative Medicine (NCCAM) in 1998 to support scientific research and disseminate evidence-based safety and effectiveness information on CAM practices.

The widespread popular interest in, and utilization of, alternative and complementary therapies has led to a corresponding movement in the mainstream medical and scientific communities to incorporate these modalities into existing realms of teaching, clinical practice, and research. Attempts at trying to develop a nomenclature for these modalities in the 1990s led to terms such as "unconventional," "nontraditional," "unorthodox," and "holistic." These terms had the characteristic of revealing cultural values and judgments regarding the appropriateness and legitimacy of these therapies and treatments (10). "Complementary medicine" refers to the use of modalities *in conjunction with* conventional medicine, such as the use of acupuncture in addition to the usual care to control and lessen pain. "Alternative medicine" refers to the use of treatments and therapies *in place of* conventional medicine. Over the past decade, the most widely accepted term has been "complementary and alternative medicine" (CAM). The NCCAM defines CAM as "a group of diverse medical and health care systems, practices, and products that are not generally considered part of conventional medicine" (11). More recently, the term "integrative medicine" has become increasingly utilized. This designation reflects the attempt to assimilate legitimate CAM therapies into the continuum of mainstream health care. It refers to a practice that combines both conventional and CAM treatments for which there is evidence of safety and effectiveness. According to Snyderman and Weil (12), integrative medicine "has a far larger meaning and mission in that it calls for restoration of the focus of medicine on health and healing and emphasizes the centrality of the patient–physician relationship."

This chapter gives an overview of the most prevalent CAM modalities, reviews common CAM products and treatments that may have implications for the otolaryngology patient, and reviews CAM treatments for common otolaryngologic problems. Evidence on both the safety and efficacy of CAM modalities continues to evolve. Health care practitioners must be aware of the use of natural products

because of potential adverse effects and interactions with other medications. This chapter does not attempt to present every CAM product or therapy used for an otolaryngologic problem. Rather, it focuses on those modalities that have the most evidence, with an emphasis on randomized controlled trials (RCTs). In this chapter, the authors are in no way advocating the use of the therapies discussed. Knowledge of the clinical efficacy as well as adverse effects of these treatments is necessary so that otolaryngologist/head and neck surgeons can appropriately guide their patients, especially since most individuals using CAM therapies do not disclose their use to their physicians. Possessing an understanding of CAM practices and treatments improves physician–patient communication and enables the health care practitioner to better serve his or her patients.

TYPES OF CAM

The myriad and diverse products and practices that encompass CAM are often organized into broad categories, such as natural products, mind–body medicine, manipulative and body-based practices, whole medical systems, and other CAM practices. Natural products include herbal medicines, vitamins, and minerals. Mind–body medicine includes meditation, yoga, prayer, and biofeedback. Manipulative and body-based practices include spinal manipulation and massage therapy. Whole medical systems include Ayurveda, traditional Chinese medicine (TCM), homeopathy, and naturopathic medicine. Other CAM practices include a range of movement therapies as well as energy therapies. These categories are somewhat overlapping, and some CAM practices may fit into more than one domain. For example, acupuncture is often categorized within mind–body medicine, but has elements like TCM, manipulative and body-based practices, as well as energy medicine (11).

Natural Products

CAM natural products include the use of herbal or botanical medicines, vitamins, and minerals. This domain also includes probiotics, which are live organisms—usually bacteria—that may confer beneficial effects to their hosts. Probiotics are available in foods, such as yogurt, or as dietary supplements. Herbs or botanicals with medicinal qualities represent some of the earliest attempts to improve health and well-being. They are the foundation of most folk remedies and are the cornerstone for many medical systems. A number of modern drugs used in mainstream medical practice were derived from plant sources. For example, the malaria treatments quinine and artemisinin were isolated from the bark of the genus *Cinchona* (a tree native to South America) and the plant *Artemisa annua* (an herb described in "Traditional Chinese Medicine"), respectively.

Many natural products are sold over the counter as dietary supplements and represent the most popular form of CAM use among both adults and children in the United States. The 2007 NHIS found that 17.7% of American adults had used a nonvitamin/nonmineral natural product in the last year (3,11). The most commonly utilized product among adults was fish oil or omega-3, which was used by 37.4% of those who reported using natural products. Other prevalently used natural products included glucosamine (19.9%) and echinacea (19.8%). Over one in ten of those surveyed reported using ginkgo biloba.

Mind–Body Medicine

These approaches focus on the relationship of the mind and body, brain and behavior. Many ancient and indigenous medical systems emphasize this interconnection. Over time, the theory advanced by Descartes of a separation of mind and body became a dominant concept among Western physicians, psychiatrists, and psychologists. Scientific healing in the form of drug therapy and surgery evolved to become the primary Western form of treatment. Over the last several decades, there has been a reemphasis in exploring the mind's ability to affect the immune system as well as other organ systems. The fundamental tenets of mind–body medicine are the concept of treating the whole person and that individuals can be active participants in their own health care (13).

Mind–body techniques include psychotherapy, relaxation, meditation, hypnosis, biofeedback, and yoga. Psychotherapy refers to the treatment of emotional and mental health, which is interwoven with physical health. Relaxation techniques aim to manage and reduce stress. Meditation is a self-directed practice for the purposes of relaxing the mind and body. Some meditation techniques involve focusing attention on single thoughts or words, while others entail focusing on a physical experience such as a breath or a specific sound. All meditation techniques share a common goal of calming mental activity, incessant thoughts, and negative reactions to one's environment or circumstances. In hypnosis, an altered state of mind is induced in which the patient enters into a state of deep and focused concentration and is receptive to specific suggestions. Biofeedback involves the use of instruments that translate physiologic processes into audio or visual signals. Patients can adjust their mental processes to control brain wave activity and bodily processes previously thought to be involuntary by observing monitoring devices. The origins of yoga date back to about 1500 BC in present-day India and Pakistan. As the practice of yoga spread throughout the world, myriad schools of thought and styles of practice have developed. Many people now understand yoga to be a practice of postures, breathing exercises, and cleansing practices, but at its root yoga is the mental process and discipline through which the human consciousness is unified with the divine consciousness (14). The practice of yoga

attempts to achieve harmony between the individual and surrounding universe by bringing the physical body under the control of the mind.

Acupuncture may also be categorized within mind–body medicine. Derived from TCM techniques, acupuncture is a family of procedures involving the stimulation of specific points located along channels corresponding to the flow of energy through the body. Traditionally, these acupoints were stimulated using fine filiform needles (0.12 to 0.46 mm diameter) to penetrate the skin. Modern acupuncture has evolved to include the application of electric currents, pressure, and low-intensity lasers to stimulate the acupoints. Moxibustion is often utilized in combination therapy with acupuncture. Moxibustion involves using heat either on or close to the skin to affect the flow of energy in the channel (15).

Several mind–body techniques were among the most commonly used CAM therapies used by American adults in the 2007 NHIS. The survey found that 12.7% had used deep-breathing exercises, 9.4% had practiced meditation, and 6.1% had practiced yoga in the past 12 months (3). An estimated 3.1 million adults and 150,000 children had used acupuncture, a 48% increase compared to the 2002 NHIS.

Manipulative and Body-Based Practices

Manipulative and body-based techniques focus primarily on touching, massaging, and manipulating the physical body to provide healing (16). Common therapies in this domain are osteopathic or chiropractic spinal manipulation and massage therapy. The 2007 NHIS estimated that 8.6% of American adults and 2.8% of children used osteopathic or chiropractic manipulation, while 8.3% of adults and 1% of children had used massage (3,11). Movement-based therapies include Feldenkrais bodywork, Alexander technique, Trager Psychophysical Integration, Aston patterning, and Pilates.

Osteopathic Medicine

Osteopathic medicine was developed by the allopathic physician Andrew Taylor Still in 1874 when he became disenchanted with the crude techniques and harmful effects of the medicines used by doctors practicing along the 19th century American frontier. After the American Civil War, during which he practiced allopathic medicine while serving as a hospital steward in the Kansas Infantry, Still became disaffected with conventional medicine in 1864 after three of his children died in a meningitis epidemic. He quit medical practice and devoted time to investigate the relationship between structure and function in the body. By 1874, he had defined the principles and philosophy of practice of osteopathy. Still's primary tenet was that structural abnormality causes functional abnormality, leading to illness. Treatments were designed to use the body's own resources. Manipulation was used to promote appropriate blood delivery, lymphatic return, and transmission of neural impulses to restore health (17). Common forms of osteopathic manipulative treatment (OMT) used today include high-velocity low-amplitude thrust, muscle energy, counterstrain, and cranial osteopathy. Craniosacral therapy is a simpler variant of cranial osteopathy that is practiced by nonphysicians such as physical therapists and massage therapists.

Osteopathy has evolved differently in the United States and in other parts of the world. Internationally, osteopathic medicine has diverged into two branches, nonphysician manipulative medicine osteopaths and osteopathic physicians practicing the full scope of medical practice. In the United States, osteopaths always have been physicians and have the same practice rights as allopathic physicians. Current practitioners implement the osteopathic medical philosophy to varying degree along a continuum of medical care (17). Only a small percentage of osteopathic physicians limit their practice to OMT, many practice no manipulation at all, and some do not believe in the clinical efficacy of OMT at all.

Chiropractic Medicine

Daniel David Palmer, a self-taught healer in Davenport, Iowa, founded the chiropractic profession in 1895. Palmer believed that the body had "innate intelligence", or a natural healing ability (18). He theorized that "vertebral subluxation" (spinal misalignment causing abnormal nerve transmission) was the cause of disease, and that chiropractic adjustment (manual manipulation of misaligned vertebrae) was its cure (19). The American Chiropractic Association defines chiropractic as "a health care profession that focuses on disorders of the musculoskeletal system and nervous system, and the effects of these disorders on general health" (20). Chiropractors manually adjust the spine to reestablish motion in the vertebral column in order to restore the normal functioning of the nervous system, which serves as the foundation for health and well-being (21).

Chiropractic has engendered controversy from the outset. In the first chiropractic adjustment, Palmer restored the hearing of Harvey Lillard, a janitor in Palmer's office building who had been deaf for 17 years. Palmer touted chiropractic as a drugless system of healing and as a cure for almost all human ailments (19). Over time, philosophical differences have evolved within the chiropractic profession. A minority of chiropractors adhere to Palmer's conservative philosophy, relying on deductions from irrefutable doctrines and rejecting scientific reasoning. These practitioners believe that chiropractic adjustment should not be combined with other types of therapy. Most chiropractors, however, seek to combine chiropractic philosophy and scientific principles with a holistic paradigm of health. The mainstream chiropractor, therefore, may incorporate modalities such as nutrition and lifestyle counseling, stress management techniques, acupressure, soft tissue manipulation, and homeopathy.

Chiropractic has developed into the third largest independent health profession in the Western world, after allopathic medicine and dentistry. It is recognized as the largest, most regulated, and best recognized of the CAM professions (22). It is estimated that 30% of all CAM practitioner visits are to chiropractors (2). Many chiropractors, however, view themselves as practicing in the realm of integrated medicine or mainstream medicine and do not view themselves a CAM practitioners (23). Chiropractic training requires 4 years of study, with rigorous educational standards supervised by government-recognized accrediting agencies. In the United States, passage of the National Board of Chiropractic Examiners written examination is recognized or required in all 50 states. Most patients go to chiropractors for musculoskeletal problems, with 60% presenting with low back pain and the remainder with head, neck, and extremity symptoms (22).

Massage

Massage as a therapeutic technique dates back thousands of years, with references evident in the writings of ancient Greece (Hippocrates), Egypt, India, and China among other civilizations. Although there are many styles and techniques, massage therapy is based on the principle that the body functions best when arterial supply as well as venous and lymphatic return are unimpeded. Muscle tightness and pain may arise if this flow is hindered. The basic techniques of massage—effleurage, pétrissage, tapotement, friction, and vibration—are directed at the skin, fascia, and muscles and are designed to restore proper fluid dynamics (24). Effleurage is a gliding stroke applied with light to moderate pressure frequently used to start a session or to link between other techniques. Pétrissage massage movements are applied with deeper pressure to lift and compress the underlying fascia and muscle in a kneading motion. Tapotement involves a rhythmic percussion of rapid, repeated taps or blows administered with the edge of the hand, cupped hand, fist, or fingertips. Friction is a technique in which the tips of the fingers or thumbs are used in a circular motion. Vibration involves use of the hands in a light, quivering motion or a mechanical oscillator. Specific styles include Swedish massage, sports massage, acupressure, Shiatsu, trigger point massage, and reflexology.

Massage therapy is becoming increasingly popular in the United States. The 2007 NHIS showed a 66% increase in prevalence of use compared to 2002 estimates (3). There are approximately 1,500 massage therapy schools and training programs in the United States. As of 2010, 43 states had laws regulating massage therapy. Regulations are increasing with states are increasingly requiring that massage therapists meet minimum training requirements at an accredited institution, pass a national exam, complete continuing education requirements, and carry malpractice insurance (25).

Whole Medical Systems

Whole medical systems are complete systems of theory and practice that evolved over time outside of conventional allopathic medicine. Ancient whole medical systems include Ayurveda and TCM. More modern systems that developed over the last several centuries include homeopathy and naturopathy. In the 2007 NHIS, homeopathy ranked as the tenth most commonly used CAM therapy among adults (1.8%) and fifth among children (1.3%) (3).

Ayurveda

Ayurvedic medicine originated during the Vedic period (2000 BC) of ancient India. The word *Ayurveda* is a compound of two Sanskrit words: *Ayus*, which means "life" or "life span," and *Veda*, which means "knowledge" or "science." Ayurveda, translated as "the science or wisdom of long life," is a holistic system of health care that emphasizes wholeness (26). Treatment approaches cover the full range of a patient's life: mind, body, behavior, environment, and consciousness (27). In Ayurveda medicine, understanding the patient's mind and body type are essential to diagnosis and treatment. Therapeutic qualities of diet and techniques to balance emotions are emphasized. Ancient Ayurvedic texts contain both an extensive materia medica on the use of medicinal plants and writings on surgery and surgical instruments. One of the eight main disciplines of Ayurveda encompasses otolaryngology-head and neck surgery as well as ophthalmology. Sushruta, a surgeon who practiced and taught along the Ganges River between 800 BC and first century AD described skin flaps, rhinoplasty techniques, and pedicled cheek and forehead flaps for nasal reconstruction (28,29).

Ayurveda is grounded in the metaphysics of five great elements—earth, water, fire, air, and ether—that comprise the universe, including the human body. Three bodily humors, *doshas*, are derived from the elements and govern the functioning of the body. The doshas are *Vata*, which governs flow, motion, and homeostatic mechanisms; *Pitta*, which regulates bodily functions related to heat and metabolism; and *Kapha*, which controls structure, cohesion, and growth (27). It is believed that a harmony between the three doshas is necessary for optimum health and to maintain the body's natural state of balance. Ayurveda places great emphasis on strategies to prevent illness. Modalities for the treatment of disease involve rebalancing the patient's doshas.

Traditional Chinese Medicine

The history of TCM dates back thousands of years, with its origins linked to mythical emperors said to have lived around 2900 to 2600 BC. Shen Nong, or the Devine Farmer, is considered the originator of Chinese herbal medicine. The *Devine Farmer's Materia Medica* (*Shen Nong Ben Cao Jing*) was written around 220 AD and is the earliest known Chinese pharmacopeia with some 365 entries

of medications (30). Huang Di, the Yellow Emperor, is known as the originator of TCM. The *Yellow Emperor's Inner Classic* (*Huang Di Nei Jing*) was compiled around 200 to 100 BC and is considered the fundamental doctrinal source for Chinese medicine.

Chinese medicine is rooted in Taoist philosophy with the fundamental concepts of *yin*, *yang*, and *qi*. Yin and yang convey "the idea of opposing but complementary phenomena that exist in a state of dynamic equilibrium" (31). Yin represents dark, night, cold, female, water, and inside. Yang represents light, day, hot, male, fire, and outside. There is equilibrium between yin and yang in the body. The concept of qi is very broad and can be translated in many ways, but it fundamentally refers to the vital energy or life force throughout the body and the universe. TCM describes 12 bodily organs. These organs are divided into six solid organs (viscera) and six hollow organs (bowels), which are paired in a yin–yang or interior–exterior relationship. Each viscus and bowel has an associated channel that runs through the organ, its paired organ, across the body, and connects with the channel of its related organ. There are 12 regular channels as well as extra channels, divergent channels, and collaterals. Qi is understood to circulate in these channels and can be influenced by accessing 361 specific holes or points that lie along the path of 14 channels (12 regular, 2 extra). Disease can arise when there is an imbalance of yin and yang. Modulating the flow of qi can reestablish balance and restore health and well-being.

Therapeutic modalities in TCM include acupuncture, moxibustion, cupping, bleeding, massage (*tui na*), qigong, and herbal medicine. Acupuncture and moxibustion are described separately in this chapter. Cupping refers to the use of a heat to induce a vacuum in a small glass or bamboo cup, which is applied as a suction to the skin to bring blood and lymph to the skin surface. Bleeding is performed to drain a channel or to remove heat from the body. Chinese massage refers to manual stimulation of acupressure points. Qigong aims to manipulate qi through breathing, physical activity, and mind awareness. Qigong practices may range from meditative systems to martial arts (31). Contemporary herbal therapy in TCM is comprised of approximately 500 herbs, with about half used frequently in formulations combining 3 to 25 herbs.

Homeopathic Medicine

Homeopathy is a whole medical system that seeks to stimulate the body's ability to heal itself by giving very small doses of diluted substances. This therapeutic system was developed by the German physician Samuel Hahnemann at the end of the 18th century. Hahnemann articulated two main principles. First, the law of similars (*similia similbus curaentur*), or "let likes be cured by likes," states that a disease can be cured by a substance that produces similar symptoms in healthy people. The law of minimum dose states that the lower the dose of the medication, the greater the potency. In a process referred as potentiation, homeopathic remedies are diluted in a stepwise fashion and shaken vigorously between each dilution. Many homeopathic medicines are diluted beyond the molecular threshold of Avogadro's number with no molecules of the healing substance remaining. Homeopaths believe that the substance leaves its essence or imprint, stimulating the body to heal itself. Hahnemann developed his philosophy after a series of experiments in which he ingested therapeutic doses of chincona bark and experienced symptoms similar to the intermittent fever of malaria. He hypothesized that giving a remedy that mimicked a patient's symptoms reinforced the body's ability to heal.

In the United States, homeopathic remedies are prepared according to the guidelines of the *Homeopathic Pharmacopeia of the United States* and are regulated by the U.S. Food and Drug Administration. Most homeopathic remedies are regulated in the same manner as nonprescription drugs. Since homeopathic products contain minimal to no active ingredients, they do not undergo the same safety and efficacy testing as other over-the-counter drugs. According to the 2007 NHIS, an estimated 3.9 million adults and 900,000 children in the United States used homeopathy in the previous year (3). In many areas of Europe, homeopathy is the most popular form of CAM: 25% of all German physicians use homeopathy, 32% of primary care physicians use it in France, and up to 42% of physicians in the United Kingdom refer patients to homeopaths (32).

Naturopathic Medicine

The foundations of naturopathic medicine may be traced back to Hippocratic practitioners who first used the term *vix medicatrix naturae*, or "the healing power of nature," to describe the body's ability to heal itself. Other philosophical influences include the hydrotherapy movement (use of hot and cold water for health maintenance and disease treatment), nature cure (natural living, vegetarian diet, use of light and air to improve health), Christian Science (religious study, spirituality, and prayer in the treatment of disease), homeopathy, osteopathy, and chiropractic. These eclectic threads were woven into a comprehensive Western system of natural medicine with professional practitioners in the late 19th century by Benedict Lust, who himself had formal training in hydrotherapy, osteopathy, chiropractic, massage, and homeopathy.

Naturopathic medicine emphasizes health promotion, disease prevention, patient education, and patient self-responsibility (33). Naturopathy is not defined by any particular therapy but by the philosophical principles of the practitioner. The concepts of vitalism (life is more than the sum of its biochemical parts) and vix medicatrix naturae (the body has the innate intelligence to heal itself) are fundamental to the practice of naturopathic medicine. In 1989, the American Association of Naturopathic Physicians defined seven core principles of naturopathic medicine, including

1. The healing power of nature (*vis medicatrix naturae*)
2. First do no harm (*primum non nocere*)
3. Find the cause (*tolle causam*)
4. Treat the whole person
5. Preventive medicine
6. Wellness and health promotion
7. Doctor as teacher (*docere*)

Naturopathic doctors are trained as family physicians, but may also practice as specialists with additional training. The scope of practice, therefore, may include primary care, botanical medicine, homeopathy, nutritional medicine, acupuncture, Ayurvedic medicine, Chinese herbal medicine, spirituality, counseling, midwifery, and minor surgery.

Other CAM Practices

CAM also includes a wide range of movement therapies and energy techniques. The Feldenkrais method is a system of movement and manipulation aimed at enhancing awareness through movement and reestablishing proper balance and neuromotor patterning. The Trager Approach is a system of movement education in which gentle, rhythmic movement and touch is taught to enhance psychophysical integration and improve physical mobility and performance. Rolfing, also known as structural integration, is a system of soft tissue manipulation and movement education based on the interaction of the human body with earth's gravity. The Alexander Technique is a method that coordinates breath, posture, and movement. Energy work involves techniques to manipulate the life force or vital energy of the patient. Examples of energy work include qigong, Reiki, therapeutic touch, and healing touch.

CAM FOR THE OTOLARYNGOLOGIST

Prevalence of CAM Use in Otolaryngology Patients

Patients with otolaryngologic complaints commonly use complementary and alternative therapies. In a survey of 1,789 patients presenting to an academic otolaryngology practice in Scotland, 35% had used a CAM treatment in the last 12 months and 18% had used the therapy for an ear, nose, or throat condition (34,35). Less than half of the patients disclosed CAM use to their physicians. The same group found similar responses in their rhinology and head and neck oncology subspecialty clinics (36,37). A study performed at an academic rhinology practice in Canada found that 16% of patients diagnosed with chronic rhinosinusitis had used a CAM therapy for their condition (38). Another recent Canadian study of patients presenting with thyroid nodules to a head and neck oncology practice found that approximately one-half were on CAM oral supplements and one-third of the patients reported using supplements known to affect hemostasis (39). Other investigators in the United States and Europe have found lower prevalence of CAM use in head and neck oncology patients ranging from 6 to 23% (40,41).

Practice Implications

Patients may not inform their physicians regarding CAM use for a number of reasons. They may believe that products are "natural" and thus pose no potential for harm. They may be concerned that the physician might impose judgment for not using mainstream therapy, or they may doubt the physician's knowledge and ability to provide advice regarding CAM products. Although rare, the use of CAM products has the potential—both theoretic and documented—to negatively impact prescribed medical and surgical treatments. A recent survey of 844 patients presenting to an outpatient clinic revealed that 15% were using herbal medicines and 40% of these had potential herb–drug interactions (42).

Drug–Herb Interactions

Although a complete list of potential herb–drug interactions is beyond the scope of this chapter, some general guidelines and common interactions are discussed. The reader is referred to the resources listed in Table 20.1 to research specific effects and interactions. In the United States, the practitioner should report all suspected adverse events to the United States Food and Drug Administration's (FDA's) Medwatch Program (*http://www.fda.gov/medwatch*) and should encourage patients to inform use of supplements to their pharmacists. When reviewing the literature regarding herbal treatments, one must remember that the evidence is largely anecdotal and based on case reports (43). The preparation of supplements is not regulated by the FDA. There is heterogeneity in both potency and purity

depending on where the plant was grown, what part of the plant was used, how it was processed, and what active ingredients are in the preparation (44).

Drug–herb interaction is defined as a pharmacologic or clinical response to the coadministration of an allopathic medication and a herbal product (45). The interaction may magnify or reduce the effect of the pharmaceutical due to altered absorption, distribution, metabolism, or excretion (46). Interactions may lead to toxicity or lack of efficacy and complicate dosing of long-term medications. This is especially concerning for drugs with narrow therapeutic indices such as warfarin and digoxin in which improper dosing may be life threatening (46,47). Special care should be taken with warfarin, as it is the most common cardiovascular medication reported to have drug–herb interactions (43) even though there is no definitive evidence that warfarin metabolism is affected by herbal supplements and natural products other than vitamin K and, potentially, ginseng and St. John's wort (48).

Herbal and nutritional supplements alter drug metabolism by various means. Cytochrome P450 (CYP) is an important hepatic enzyme system that has been implicated in a number of drug–herb interactions. CAM therapies that induce CYP include St. John's wort, garlic, and flavonoids (49). These medications may decrease serum concentration and efficacy of a myriad medications metabolized by the liver (49). Other supplements such as grapefruit, goldenseal, echinacea, piperine, ginkgo, and licorice may inhibit CYP and thus potentiate drug effects (44,50,51). There are, however, a number of CYP isoforms, and the interaction of herbal supplements with this system is complex; each active ingredient may simultaneously activate some isoforms while inhibiting other isoforms.

The use of CAM natural products may alter the bioavailability of prescription drugs by modifying absorption via changes in gastrointestinal pH, motility, and enterocyte activity (46). Examples include fiber, bentonite clay, charcoal, and acacia (44,51). Garlic and St. John's wort may also affect drug bioavailability by interacting with P-glycoprotein, a drug transporter expressed by intestinal enterocytes (46). Potential interactions of some popular natural products are listed in Table 20.2.

Perioperative Management

The surgeon also must be cognizant of the potential for perioperative complications related to therapy with herbal supplements and natural products. Studies have reported that between 7% and 22% of adult presurgical patients use herbal medications (55). CAM treatments have the potential to alter anesthetic drug metabolism. Alterations in physiologic processes by herbal therapies with potent cardiovascular (e.g., ma huang), neurologic (e.g., kava), or other systemic effects may also pose risks for the patient under general anesthesia (56,57).

TABLE 20.2 POTENTIAL DRUG INTERACTIONS OF COMMON HERBAL SUPPLEMENTS AND NATURAL PRODUCTS

Supplement	Common Uses	Potential Interaction
Co Q-10	Cardiovascular	Structural similarity with vitamin K—may decrease effects of warfarin (52)
Echinacea	Upper respiratory tract infections	No specific interactions reported but recommended caution with autoimmune disease, immunosuppression (steroid therapy), tuberculosis, alcohol use (disulfiram reaction) (52–54)
Fish Oil	Cardiovascular protection	Anticoagulant and antiplatelet drugs (theoretical risk of bleeding with high doses) (53)
Garlic	Hyperlipidemia, prevention of atherosclerosis	Protease inhibitors (saquinavir), anticoagulant and antiplatelet drugs, hypoglycemics (51,52)
Ginkgo biloba	Erectile dysfunction, improvement of cognitive and physical function	Thiazides, nifedipine, anticoagulant and antiplatelet drugs, trazadone (increased sedative), caution with seizure disorder (51,52)
Ginseng	Energy, fertility	Anticoagulant and antiplatelet drugs, lithium and neuroleptics (irritability, sleeplessness, manic behavior), hypoglycemics, estrogenics, caution with autoimmune disease, immunosuppression, hypertension (52–54)
Glucosamine	Osteoarthritis	May increase international normalized ratio (INR) in patients taking warfarin (52)
Melatonin	Insomnia, reproductive function	May decrease nifedipine; nonsteroidal anti-inflammatory drugs (NSAIDs), antidepressants, beta agonists and antagonists, scopolamine, and valproate may alter melatonin metabolism (52)
St John's wort	Depression	Serotonin syndrome with neurologic and psychiatric drugs, reduction of serum concentration of drugs metabolized by CYP (digoxin, birth control, cyclosporine, protease inhibitors, warfarin, theophylline, anticonvulsants, etc.), caution with immunosuppression (52,54)

One of the most pertinent issues related to herbal therapy for the surgeon is altered hemostasis. A recent review identified documented or theoretical alterations of platelet function by 42 herbal products, the coagulation cascade or warfarin metabolism by 60 herbal products, and coagulation effects by 20 nutritional supplements (55). This review and other reports are largely based on case reports, but the potential implications cannot be ignored and the American Society of Anesthesiology recommends that patients stop all herbal medications 2 to 3 weeks before an elective surgical procedure (55,57). Guidelines produced by the British Association of Day Surgery recommend stopping ginseng, garlic, ginkgo, and St. John's wort 1 week prior to surgery and stopping echinacea if immunosuppression is required (54). Commonly implicated supplements that may alter hemostasis include garlic, ginger, flax seed oil, ginkgo biloba, ginseng, vitamin E, and eicosapentaenoic acid (omega-3 fatty acid) or fish oil (56,58).

These studies and recommendations should be interpreted with caution as recent data suggest herbal therapies and nutritional supplements may not affect hemostasis to the extent as historically reported. One *in vivo* study found no effect on platelet function based on PFA-100 assay after 2-week administration of ginkgo biloba, garlic, Asian ginseng, St. John's wort, and saw palmetto at their recommended doses (59). Similarly, although garlic inhibits platelet aggregation *in vitro* (60), consuming garlic at dietary doses may have no effect on platelet activity in healthy individuals (61).

Another perioperative consideration is the effect of herbal and nutritional supplement therapy on wound healing. Echinacea may theoretically reduce wound healing by affecting the immune system, and some caution against its use in the perioperative period (50,54,56). Some report improved wound healing with certain herbal therapies and nutritional supplements such as bromelain, grape seed extract, and vitamins A, C, and E (50,58). One randomized, placebo-controlled crossover study found that consumption of an oral supplement containing proteolytic enzymes, bromelain, grape seed, rutin, vitamin C, calcium, and potassium accelerated skin wound healing time by 17% (62).

COMMONLY USED CAM THERAPIES FOR OTOLARYNGOLOGIC CONDITIONS

The following section reviews the evidence for some of the most commonly used CAM therapies for disorders of the ear, nose, and throat. When possible, we highlight treatments with the most robust data.

Tinnitus

Practitioners and patients have turned to a variety of alternative therapies for tinnitus due to its high prevalence and the limited effectiveness of allopathic strategies for treatment. Ginkgo biloba is thought to have a variety of beneficial effects on the central nervous system and has been commonly used for tinnitus. Although initial reports were promising, its efficacy has not been substantiated by RCTs and meta-analyses (63–65). Acupuncture continues to be used for tinnitus, with patients often reporting subjective improvement, but studies indicate this therapy is no better than placebo (66,67). Myriad multiherb and vitamin preparations are also widely advertised for the treatment of tinnitus. The majority purport to increase microcirculation of the inner ear, improving hearing and tinnitus. Lipoflavonoid is a commonly used preparation that is a combination of eriodictyol glycoside, bioflavonoids, vitamin B_6/B_{12} complex, vitamin C, niacin, riboflavin, thiamine, choline, inositol, and pantothenic acid. A brief review of the literature does not reveal any current evidence supporting its claims of efficacy.

Vertigo

Similar to tinnitus, the treatment of vertigo with CAM mainly has been through the use of herbal supplements that theoretically increase microcirculation of the inner ear. Betahistine, a histamine analog, has been proposed to increase vestibular blood flow and reduce the symptoms of vertigo compared to placebo (68–70). Vertigoheel is a popular remedy composed of four active ingredients—ambra grisea, cocculus indicus, conium maculatum, and petroleum (71). It is believed to improve microcirculation and activate vestibular regulatory systems within the brainstem (72). In 1998, an equivalence trial showed therapeutic equivalence between vertigoheel and betahistine in the reduction of frequency, duration, and intensity of vertigo over a 6-week treatment period (73). The significance of such a trial is unclear, as betahistine has not proven to be an effective agent and is thus a poor control (74). A more recent study comparing the use of vertigoheel to ginkgo biloba for the treatment of atherosclerosis-related vertigo found that both therapies improved tinnitus equivalently (75). Overall, the evidence for possible efficacy of vertigoheel is encouraging but limited, and more data is needed. Other CAM treatments for vertigo include ginger (antiemetic), hawthorne berry (increased cardiac output), and t'ai chi (increased balance) (72,76).

Otitis Media

In 2004, the American Academy of Pediatrics and American Academy of Family Practice jointly issued clinical practice guidelines for the management of acute otitis media (AOM), citing observation as an option for the management of nonsevere AOM in children above the age of 2 years (77). This recommendation is based on data showing high likelihood of uncomplicated spontaneous resolution of disease and concern regarding increasing antimicrobial resistance (78). Practitioners espouse these

principles when advocating CAM treatments for AOM (79). However, neither the clinical practice guidelines for AOM nor otitis media with effusion (OME) report any specific recommendations regarding CAM treatments due to insufficient and controversial data (77,80). The guidelines caution that almost any intervention can be shown to be beneficial unless judicious "parallel-group, randomized, controlled trials with valid diagnostic methods and adequate sample sizes" are used. Furthermore, CAM techniques should be used with caution as complications have been reported (77,80). Regardless, CAM therapies are frequently employed for the treatment of both AOM and OME.

Common botanicals employed for the treatment of otitis media include chamomile, echinacea, marshmallow, and mullein (79). Homeopathic practitioners use a variety of herbal preparations that are chosen and individualized based on the patient's clinical presentation and symptom profile. A pilot study on individualized homeopathy for AOM reported a statistically significant reduction of symptoms compared to placebo, but no difference in treatment failures between the groups (81). Naturopathic doctors also use a variety of different herbal preparations to treat AOM. A double-blind RCT compared the treatment of AOM with three therapies in various combinations: naturopathic herbal extract ear drops (NHED), a topical anesthetic, and oral antibiotics. The aim of this study was to explore means of symptom relief in the first 2 to 3 days of infection before antibiotics could affect the disease course. The authors found that NHED without antibiotics engendered improved pain control compared to NHED with antibiotics, but time was the greatest contributor to symptom reduction. They concluded that herbal preparations may be beneficial during the observational period of AOM, but the study was criticized for lacking an antibiotic-alone control group (82).

Xylitol is a sugar alcohol that has been found *in vitro* to inhibit pneumococcal growth and adhesion to nasopharyngeal walls (83,84). Xylitol in solution and as a chewing gum have been shown to reduce the number of AOM episodes and the need for antibiotics in blinded RCTs (84,85). Study subjects, however, took the medication five times a day for 2 to 3 months. Rare side effects included abdominal discomfort and osmotic diarrhea. More recent studies attempt to determine whether similar results can be achieved with more favorable dosing regimens. One study failed to show a difference between xylitol and placebo when given three times daily for 3 months during respiratory infection season (86). Another study showed that xylitol failed to prevent the development of AOM if started after the onset of an acute respiratory infection (87).

Zinc and cod liver oil also have been used to prevent otitis media. A recent Cochrane review reports there is no convincing evidence that zinc supplements reduce middle ear infection incidence (88). Trials have been published supporting the use of cod liver oil for the prevention of AOM but the data is limited (89).

Some osteopaths believe that restriction of the normal physiologic motion of the temporal bone may lead to eustachian tube dysfunction. They believe that normal temporal bone physiology can be restored by neurocranial restructuring, a technique in which a variety of balloons and manual maneuvers are used to rearrange cranial structure (90). One small study found that osteopathic manipulation in addition to pediatric primary care reduced antibiotic use and surgical procedure rates (91). A more recent RCT showed that neither osteopathic manipulation nor echinacea reduced the risk of recurrent AOM (92). Those who oppose neurocranial restructuring techniques cite case reports of complications (facial fractures, mortality) as well as the physiologic improbability of the technique (93).

Other CAM techniques for otitis media include lymph node drainage (manual milking of periauricular nodes), eliminating "mucus-producing" foods (wheat, dairy, eggs, corn, citrus, soy, refined sugar) from the diet, and testing for food allergies (79). Similar to many otolaryngologists, CAM practitioners commonly recommend certain lifestyle modifications such as encouragement of breastfeeding and avoidance of daycare, pacifiers, and smoking (79).

The natural history of otitis media is for spontaneous resolution without intervention in the majority of cases. Guidelines state that antibiotics should be started if there is no improvement after 48 to 72 hours of observation. Thus, the otolaryngologist who wishes to employ a CAM therapy must be convinced that, based on the current literature, there is no significant risk of harm with that particular technique. The standard of care, antibiotics, should be prescribed for persistent infection. Antibiotics should be used for all patients under the age of 2 years.

Head and Neck Oncology

Due to the often poor prognosis of head and neck cancer as well as the arduous treatment regimens of allopathic medicine, patients commonly seek CAM therapies both for the treatment of cancer itself and for side effect and symptom relief. A recent survey found that 22.7% of head and neck cancer patients in Europe utilized CAM and that their CAM use dramatically increased after cancer diagnosis (41). Most patients use CAM therapies in combination with conventional treatments rather than as an alternative to mainstream therapies (94).

Specific data on cancer treatment and prevention with CAM modalities are limited. One must remember, however, that a number of currently used chemotherapeutics were isolated from plants (e.g., etoposide, vinblastine, vincristine, taxol) and therefore research in this area remains very important. One example is recent studies on the effects of green tea as a promising supplement for cancer prevention and treatment (95). A Phase II RCT suggested possible suppression of oral premalignant lesions by green tea extract (96). Numerous oral and topical CAM therapies have also been suggested—despite very limited data—for

the prevention of skin cancer, including green tea, beta-carotene, vitamin C, vitamin E, and a low-fat diet (97).

A variety of techniques are used for cancer-related pain. A recent systematic review reported that there is a paucity of RCT data to sufficiently support the efficacy of these treatments, but that hypnosis, imagery, support groups, acupuncture, and healing touch seem promising (98). Several studies report the benefit of acupuncture to treat cancer-related pain, but a 2011 Cochrane review found that the evidence is insufficient (99). Also, in regard to radiation therapy, both topical aloe vera and honey have been shown to reduce cancer treatment-related mucositis in several RCTs (100,101). Mind–body treatments such as meditation, imagery, prayer, relaxation therapy, biofeedback, hypnosis, yoga, art and music therapy, and t'ai chi have also been used to treat the psychological and physical stress associated with cancer diagnosis and treatment (72,102).

Allergic Rhinitis and Rhinosinusitis

There are a myriad of CAM therapies for treating both allergic rhinitis (103) and chronic rhinosinusitis. Few are studied with rigorous double-blind RCTs for clinical efficacy. Often, the pharmacologic mechanisms and adverse effects are even less well understood. A few therapies for allergic rhinitis, including spirulina, butterbur, and phototherapy hold some promise.

Spirulina, the dried biomass of the blue-green algae *Arthospira platensis*, is considered safe for consumption by the FDA and is thought to inhibit histamine release from mast cells (71,104). RCTs have shown reductions in serum IL-4 levels and clinical nasal symptom scores in allergic rhinitis patients taking spirulina (105,106). Additional studies are needed to determine the efficacy and the active pharmacologic agent of spirulina.

The leaf and root extracts from the shrub butterbur (*Petasites hybridus*) have been shown to inhibit leukotriene and histamine synthesis (107) as well as mast cell degranulation *in vitro* (108). Alkaloids that are hepatotoxic and carcinogenic must be removed from raw butterbur extract before it can be used (109). In RCTs, butterbur was found to significantly improve nasal symptom scores compared to placebo (110) and to be comparable in efficacy to cetirizine (111) and fexofenadine (112,113). Another RCT, however, found no difference in symptom scores and peak nasal airflow compared to placebo (114). Moreover, butterbur did not inhibit skin-test reactivity in a study comparing butterbur to an antihistamine and placebo using skin-prick tests (115). Although preliminary data suggest butterbur may be effective in allergic rhinitis, additional studies are needed to elucidate its efficacy and safety.

Phototherapy with ultraviolet (UV) light is believed to have immunosuppressive effects, including the reduction of antigen presentation by dendritic cells, inhibition of proinflammatory cytokine synthesis and release, and induction of apoptosis in immune cells (116). A RCT investigating the use of a combination of low-dose UV-B, UV-A, and visible light in patients with ragweed-induced allergic rhinitis resulted in decreased nasal symptom scores and serum eosinophil levels (117). Phototherapy was found to be superior to fexofenadine in the reduction of rhinorrhea, nasal obstruction, and total nasal symptom scores (118). However, it has not been directed compared to intranasal corticosteroids. UV light induces DNA damage and, at high doses, is associated with carcinogenesis. The long-term effects of phototherapy on nasal mucosa are unknown.

There are fewer studies on various CAM therapies for rhinosinusitis compared to allergic rhinitis, and the existing literature is more difficult to interpret because investigators may use different definitions for acute and chronic rhinosinusitis. Two of the best-studied CAM treatments are sinupret and bromelain. Sinupret is an herbal preparation containing extracts of elder flower, primrose flower, common sorrel, vervain, and gentian root. Bioflavonoids in sinupret have been found to stimulate transepithelial chloride transport (119). For acute rhinosinusitis, one RCT comparing sinupret to placebo as an adjunct to antibiotics and a nasal decongestant showed significantly improved radiographic and patient-assessed outcomes (120) while another RCT found no difference between sinupret and placebo (121).

Bromelain is the crude extract from the stem and immature fruit of pineapple. It contains concentrates of closely-related proteinases and is thought to prevent and reduce edema, promote absorption of antibiotics, and induce production of cytokines (122). A meta-analysis of two RCTs found that bromelain decreased nasal mucosal inflammation, nasal discomfort, breathing difficulty, and overall symptom scores compared to placebo (123). A number of other herbal treatments have single studies showing positive effects for rhinosinusitis, but these results have not been replicated (123).

Honey made from the nectar obtained from manuka, a small tree native to New Zealand, is believed to have antibacterial and antifungal properties attributed to the active ingredient methylglyoxal (124). Recently, manuka honey has been shown to be effective against the biofilms of *Pseudomonas aeruginosa* and *Staphylococcus aureus*, including methicillin-resistant *S. aureus* (125). Treatment of honey solution in an animal nasal mucosal model did not show evidence of histologic epithelial injury (126). In an RCT assessing the use of a sprayed manuka honey solution in patients with allergic fungal rhinosinusitis, patient-assessed symptom scores improved in those treated with honey, but there were no differences in culture results or endoscopy scores (127). The authors of this chapter are currently conducting a RCT comparing topical nasal irrigations with manuka honey solution to culture-directed oral antibiotics for acute exacerbations of chronic rhinosinusitis.

CONCLUSION

This chapter reviewed some of the main types of CAM utilized by patients. Possible drug–herb interactions as well as perioperative issues are discussed. Finally, the existing evidence for CAM therapies used for ear, nose, and throat diseases are reviewed. Given that a large number of patients use CAM therapies, it is important that the practicing otolaryngologist should have some insight into the world of CAM.

HIGHLIGHTS

- According to national surveys, the prevalence of CAM use is approximately 40% for adults and 10% for children in the United States.
- Use of CAM therapies is increasing.
- About half of patients using CAM treatments do not inform their physicians of such use.
- Herbal medicines have the potential to alter the absorption and metabolism of conventional pharmaceutical drugs, especially those metabolized by the hepatic CYP system.
- Herbal medicines that may alter hemostasis should be held 1 to 2 weeks prior to surgery.
- A number of CAM therapies are commonly used for otolaryngologic disorders. Most of these have not been studied rigorously, and questions remain regarding their safety and efficacy.

Tobacco Cessation: How-to Guidance and Resources for Practitioners

21

Henry R. Diggelmann *Grant S. Hamilton III*

BACKGROUND

Smoking tobacco is the single most preventable cause of death and disease in the United States (1). In 2005, smoking tobacco was responsible for 467,000 deaths, accounting for about 1 in 5 deaths in US adults (1). In the United States, an additional 8.6 million people have serious illnesses that are caused by smoking—chronic bronchitis and emphysema account for more than half of them. For every person who dies from tobacco use, another 20 suffer with at least 1 serious tobacco-related illness (2). Tobacco use also represents a huge economic burden. During the time period from 2000 to 2004, cigarette smoking was estimated to be responsible for $96 billion in direct medical costs and $97 billion in lost productivity (3).

Unfortunately, it is estimated that 46 million American adults currently smoke cigarettes (4). Even though the numbers remain high, there has been a significant decrease in cigarette smoking over the last 40 years (5). From 1965 to 2008, the percentage of the US population who smoke decreased from approximately 42% down to 20.6% (4,5). However, this decrease has leveled off over the last 5 years (4). Fortunately, of the estimated 94 million people who have ever smoked, 51.1% have now quit, and since 2002, the number of former smokers outnumbers the number of current smokers (4).

Smoking has historically been more common in men. Centers for Disease Control and Prevention data from 2008 suggest a prevalence of smoking in the United States of 23.1% among men and 18.3% among women. There is also some variability with regard to age. In general, the percentage of smokers 18 to 65 years of age does not vary significantly from the national average—however, there are significantly fewer adults over age 65 who smoke. This age group has a smoking prevalence of only 9.3%.

Tobacco use patterns also vary by socioeconomic status. The prevalence of smoking among adults with a graduate degree is only 5.7%, while the prevalence of smoking is highest among adults who had only earned a General Education Development certificate. This is consistent with data demonstrating that individuals with higher education also have a much higher awareness of the risks associated with smoking (6). Smoking is also much more common in adults living below the poverty level compared to those living above the poverty level, with a prevalence of 31.5% and 19.6%, respectively. Tobacco use is also not uniform between different ethnic groups. Asians have the lowest prevalence at 9.9%, followed by Hispanics at 15.8%, non-Hispanic blacks at 21.3%, non-Hispanic whites at 22.0%, and American Indians the highest at 32.4% (4).

The chemical primarily responsible for tobacco dependence is nicotine. Nicotine is a highly addicting drug. Its main targets in the central nervous system are neuronal nicotinic acetylcholine receptors. It also acts on the mesolimbic dopamine system, resulting in reward signaling and addiction. Its effects on the brain reduce anxiety and relieve stress, in addition to slight cognitive enhancement and increased ability to fight fatigue (7,8). Interestingly, there is a strong genetic component to nicotine dependence (9). The bioavailability of nicotine is around 12% in cigarette smoke, representing an uptake of about 1 mg of nicotine per cigarette. However, this uptake is variable depending on the method used to smoke the cigarette and can be increased to up to 40% bioavailability. It is generally considered that a dose of 5 mg of nicotine per day can result in addiction, but this is variable among individuals. Nicotine is metabolized in the liver and the principal metabolite is cotinine. Cotinine levels in blood, urine, hair, saliva, or nail can be measured and are directly proportional to the amount of nicotine the patient has recently been exposed to. Per cigarette, smokers produce 14 ng of cotinine per milliliter of blood. It is generally considered that a nonsmoker should have 3 ng/mL or less of cotinine in his or her bloodstream (10,11). The clinician can verify cessation of smoking using this test.

Tobacco cessation is a critical part of the patient encounter for the otolaryngologist. Smoking impacts patients in a multitude of ways, and efforts directed toward cessation provide the foundation of preventive medicine for all areas in the field of otolaryngology. In fact, tobacco abuse can lead to decreased olfaction, thyroid disease, rhytids, tooth discoloration, gum disease, cancer, decreased taste, voice changes, sore throat, hearing loss, and many of other conditions. Smoking also increases the rate of postoperative complications and impairs wound healing.

Head and neck cancer is directly caused by tobacco use. Smoking cessation efforts are fundamental to efforts to decrease the incidence of head and neck cancer. Multiple studies conclude that quitting smoking can lower the incidence of second malignant lesions in head and neck cancer patients from 40% down to 5% to 20%. However, this is controversial. Other data suggest that patients who have reached a critical level of damage due to prolonged tobacco exposure will not see this benefit. In this model, it is hypothesized that after a certain level of exposure, the damage caused by tobacco exposure is irreversible, even with cessation. This model also proposes that, for this reason, individuals who have the least amount of tobacco exposure will have the most benefit from cessation (12).

Secondhand smoke also poses a significant health risk. In fact, there is no level of secondhand smoke that is risk-free and the presence of any secondhand smoke carries risk of developing complications. Secondhand smoke has been proven to cause premature death and disease in both children and adults who are nonsmokers. In children, secondhand smoke results in increased risk for sudden infant death syndrome, acute respiratory infections, ear infections, and asthma. Children exposed to smoking by their parents also demonstrate slowed lung growth and suffer from respiratory symptoms. Adults exposed to secondhand smoke can develop coronary artery disease and lung cancer (13).

THE CLINICAL INTERVENTION

Smoking cessation is an integral part of today's medical practice and has received extensive investigation in the medical literature. Consequently, this area has been investigated on a scale rarely achieved in the field of otolaryngology.

In 2008, among current cigarette smokers, an estimated 45.3% of smokers tried to quit and managed to stop smoking for 1 or more days (4). Unfortunately, an unassisted attempt at smoking cessation only has a success rate of around 4%. Interventions that have been demonstrated to effectively decrease the use of tobacco include increasing price of tobacco products, instituting smoke-free policies, limiting advertisements and promotions, controlling access, and assisting and promoting users to quit (14). Herein lies the role of the physician, to assist and promote users to quit.

The physician occupies an important and unique position to intervene in smoking cessation. Unfortunately, physicians often do not take advantage of their authority, as only 37.2% of smokers reported they received advice to quit during a visit to a health care provider in the last year. This is significant as 70.2% of all smokers reported seeing a physician during the same time period (15). The responsibility of the physician is emphasized by Kreuter et al. (16), who found that smokers were 54% more likely to try to quit if a physician told them to quit. With this in mind, and with 70% of smokers reporting that they want to quit (17), a positive interaction in the physician's office is a key portion of the tobacco cessation process.

Therefore, all patients should receive guidance and advice concerning tobacco usage at every clinical visit, including current smokers, former smokers, or nonsmokers. For current smokers, it has been demonstrated that interventions that are as short as 3 minutes can significantly increase rates of tobacco cessation. This intervention should include a combination of counseling and the initiation of pharmacotherapy. It has been demonstrated that there are improved outcomes when counseling and pharmacotherapy are used in combination. While each is effective alone, cessation rates are significantly improved when used in combination (18).

BRIEF CLINICAL INTERVENTION

The Public Health Service has published extensive literature on smoking cessation and endorses the intervention commonly referred to as the "5As" (Table 21.1). This is a brief intervention to be performed in clinic that requires only 2 to 3 minutes and has demonstrated excellent results. It is composed of five parts: ask, advise, assess, assist, and arrange.

- Ask:
  - Every patient who walks into the clinic must be asked about tobacco usage. One simple way to implement this is to make tobacco use part of vital signs. Usage should also be documented in the chart. In fact, there is strong evidence that the use of "provider reminders" by health care providers improves tobacco cessation rates. These reminders could take the form of a chart sticker, vital sign stamp, medical record flow sheet, or checklist. These represent systems-based reminders to the provider to prompt the provider to discuss tobacco cessation (19).

TABLE 21.1 OVERVIEW OF BRIEF CLINICAL INTERVENTION

Ask
Advise
Assess
Assist
Arrange

- Advise:
  - Otolaryngologists should advise all patients on the risks of tobacco usage at every clinic visit. This includes nonsmokers, smokers, and former smokers. Doctors should also strongly urge all users of tobacco to quit, advise patients of the risk of continued use, and explain the benefits of quitting. All advice should be stated in a clear and strong statement. The advice should also be personalized. Discussion of personal benefits of successful cessation could include examples such as saving money, decreasing risks to others (kids), cutting personal risk, or living longer. Unfortunately, only 37.2% of smokers reported they received advice to quit during a visit to a health care provider in the last year. This is even more worrisome as 70.2% of all smokers reported seeing a physician during the same time period (15).
- Assess:
  - It is also important to ask all tobacco users "Are you willing to give quitting a try?" If the patient indicates that he or she is ready to quit now, then provide assistance to do so. At this time, either deliver or set up intensive intervention for the patient. Also initiate pharmacotherapy, and provide resources the patient can use to help. Just telling the patient to quit is not good enough. Intensive intervention has been shown to be far superior than simple advice (20).
  - For those patients who are not interested in quitting, consider motivational interviewing techniques, or any other intervention geared toward increasing the probability the patient will be ready to quit in the future. It has been demonstrated that these techniques appear to be effective in increasing the likelihood that the patient will make a future quit attempt. To perform these techniques, clinicians must proceed with four basic principles: express empathy, develop discrepancy, roll with resistance, and support self-efficacy. It is also advantageous to utilize the "5Rs," a concept that helps capture the content areas to be addressed. These include relevance, risks, rewards, roadblocks, and repetition. Under this umbrella, the otolaryngologist can begin to explore the patient's fears and begin to offer reasons and ideas that lessen the patient's resistance to change (21).
  - It is also imperative to assess the patient's readiness to change. A firm grasp of the transtheoretical model is important when dealing with any process of behavioral change. This model assesses the individual's readiness to change and is commonly referred to as the "Stages of Change." Familiarity with this model allows the clinician to more effectively communicate with patients and to tailor both the discussion and recommendations specifically to the individual patient's willingness to change.
    - The first stage of change is Precontemplation. This stage is characterized by the individual's lack of intent to take action in the foreseeable future. Patients may be in this stage because they are uninformed or underinformed, or they may have failed to quit smoking previously and now are demoralized about the prospects of succeeding. These patients will avoid thinking about or may not even be aware of their high-risk behaviors (22).
    - The second stage of change is the Contemplation stage. This stage is characterized by the individual who intends to change in the next 6 months but remains in a state of chronic contemplation as he or she weighs the pros and cons—with a majority of his or her focus on the cons. This individual may be more open to seeking out information but most likely shows ambivalence (22).
    - Preparation is the third stage and is defined by the individual who intends to take action in the immediate future, typically within 1 month. These patients have thought about a plan of action and are usually seeking information. These are excellent candidates for action-oriented programs in smoking cessation (22).
    - The Action stage is when the individual makes the modification to his or her lifestyle and continues it for 6 months. With smoking cessation, this stage represents the quit date, followed by abstinence. Unfortunately, of the six stages, this is the only stage that is actually observable to the outside individual (22).
    - After 6 months of abstinence, the patient moves into the fifth stage, Maintenance. This stage is characterized by the patient working to prevent relapse, but no longer actively changing. With smoking cessation, this stage can last years with a relapse rate at 12 months of 43%, decreasing to 7% after 5 years. This stage usually lasts as long as the change endures (22).
    - The final stage, Termination, is a theoretical goal, but not usually attained. It is defined by the individual achieving a state where there is no temptation to revert no matter his or her condition or the situation he or she is in. In this stage, it would be as if the patient had never initially acquired the habit. Unfortunately, this is rarely attained and in the setting of smoking cessation efforts has no practical use (22).
    - Some patients do relapse and restart smoking. Relapse is not a stage by itself but represents a form of regression with a return to an earlier stage. Luckily, only about 15% of patients return all the way to precontemplation. In the event of relapse, identify what stage the patient has returned to, and then immediately restart the motivational interviewing process (22).
- Assist
  - It is important to provide advice and support to those patients interested in quitting. Many steps should be taken to assist the patients in their difficult endeavor, including set a quit date, have the patient tell their family their plan, have the patient tell friends and coworkers so there are more people to provide support and encouragement, encourage the patient to remove all tobacco products, and help the patient change routines and develop a new lifestyle (Table 21.2).

TABLE 21.2 EXAMPLES OF PRACTICAL TOPICS FOR COUNSELING

- Activities that can increase the risk of relapse include stress, being around other tobacco users, or drinking alcohol.
- The patient should be warned to anticipate experiencing urges and should learn behaviors to cope with them, including distracting attention and changing routines.
- Patients should be aware of their smoking cues and the availability of cigarettes.
- Patients should learn to avoid trigger situations.
- Reduce negative moods by developing cognitive strategies.
- Change lifestyle to reduce stress and reduce exposure to smoking cues.
- Any smoking increases the chance of a full relapse.
- Withdrawal symptoms peak within 1–2 wk and include problems with concentration, mood, or urges. These can last for many months.
- Reinforce the idea that smoking is an addiction.
- Assure the patient effective treatments are available.
- Reinforce the reasons the patient wants to quit.
- Note that half of all people who have ever smoked have now quit.
- Encourage the patient to talk about the quitting process.
- Communicate your concern for the patient. Encourage the patient and build confidence in the patient.

Adapted from Clinical Practice Guideline Treating Tobacco Use and Dependence 2008 Update Panel, Liaisons, and Staff. A Clinical Practice Guideline for treating tobacco use and dependence: 2008 update. A U.S. Public Health Service report. *Am J Prev Med* 2008;35(2):158–176.

- When offering practical advice, it should be done with specific consideration to problem-solving skills. Have the patient commit to total abstinence. Review past attempts and why they did not work, what could be done differently, and use any positives from those experiences to bolster the patient's resolve. Anticipate triggers and challenges and develop strategies about how to overcome them. Encourage the patient to limit or abstain from alcohol, as the use of alcohol is associated with higher incidence of relapse. Diminish exposure to secondhand smoke, including identifying other smokers with whom the patient may have contact. Encourage other individuals at home to quit at the same time to provide both a smoke-free environment and a support system.
- One of the most important steps in assisting the patient is to set them up with counseling, specifically intensive intervention. Also, if possible, use pharmacotherapy in conjunction with the counseling. Multimodality treatment has been proven to have a higher success rate than single modality treatment. Provide supplementary materials to patients with additional information on resources and smoking cessation. Also provide support to the patient by offering your office and time as available to assist with any problems. Telephone support as a component of the intervention is strongly recommended and has been demonstrated to increase success rates for tobacco cessation (19). This could include follow-up telephone calls or informational messages left for the patient.
- Every state in the United States has a tobacco quitline. These lines offer free counseling and are able to get patients in contact with other local programs. These services can be accessed by calling either 1-800-QUIT-NOW or 1-877-2NO-FUME. The National Cancer Institute of the National Institute of Health also sponsors a quitline, 1-800-44U-QUIT. In a meta-analysis, these quitlines have been found to be effective methods of treating tobacco dependence (21).

- Arrange:
  - Follow-up appointments are crucial and should be supplemented with telephone calls. Schedule the first follow-up right after the quit date to ensure compliance and address any immediate problems. A second follow-up visit should occur shortly after. At these visits, congratulate success, identify problems, anticipate problems, encourage further intervention, and assess pharmacotherapy use and compliance. Also, remind patients of the resources available to them, and go over and reinforce the reasons why they quit. For those patients who have relapsed, review the circumstances, and make new plans to quit again.

MULTIMODALITY TREATMENT

Multimodality treatment plans are the cornerstone of tobacco cessation. These plans should consist of intensive counseling, pharmacotherapy using multiple medications if possible, access to support and counseling networks including quitlines and Web-based resources, and close follow-up.

Intensive Counseling

The first modality required to achieve success is intensive counseling. A recent Cochrane review assessed preoperative smoking interventions, specifically evaluating smoking cessation and the incidence of postoperative complications. In the analysis, the patients who had undergone brief interventions were separated from those who had undergone intensive interventions—which consisted of weekly counseling sessions over a period of 4 to 8 weeks. Surprisingly, the results were that only with intensive counseling was there a significant reduction in overall complications, wound complications, and continued smoking cessation 12 months after surgery. Brief counseling, defined as counseling during the routine preoperative assessments, did not achieve any of these results (20). These data form the foundation for the current recommendations that all patients must undergo intensive counseling sessions when considering smoking cessation. Otolaryngologists simply telling their patients they should quit, while important, is of minimal long-term value.

Pharmacotherapy

Pharmacotherapy should be used together with counseling whenever possible. Multimodality treatment has been proven to have a higher success rate than single modality treatment. However, there are certain populations where pharmacotherapy is contraindicated or there is a lack of sufficient evidence to support use. These populations include pregnant women, light smokers, adolescents, and smokeless tobacco users.

The otolaryngologist's primary pharmacologic armamentarium for smoking cessation is comprised of three medications in seven forms: bupropion, nicotine gum, nicotine inhaler, nicotine lozenge, nicotine nasal spray, nicotine patch, and varenicline. There are also a number of second-line pharmacotherapies including clonidine and nortriptyline. However, the food and drug administration (FDA) has not approved these for smoking cessation (Table 21.3).

Nicotine Replacement Therapy

Nicotine replacement therapy (NRT) is one of the cornerstones of smoking cessation. It helps control cravings, reduces withdrawal symptoms, and improves cessation success rates. There are many forms to choose from, including a patch, gum, an inhaler, a lozenge, and a nasal spray. Of these, the patch has established itself as the primary form of delivery.

The nicotine patch offers a constant level of nicotine delivery, ease of use, and a record of high levels of compliance. Dosage is one 21-mg patch every 24 hours for 4 weeks and then one 14-mg patch every 24 hours for 2 weeks, followed by one 7-mg patch every 24 hours for 2 weeks. There are also 16-hour release forms available, but they may be more difficult to use due to potential for severe morning cravings. The effectiveness of a high-dose patch is excellent with regard to abstinence rates, with an odds ratio of 1.9 compared to placebo. Adverse effects include a local skin reaction, allergic reactions, and insomnia. The potential for skin irritation can be avoided by rotating patch sites, but if it does develop, it can be treated with topical corticosteroids. The ability to titrate the dose of nicotine can also be an issue in patients who are heavy users or continue to have cravings. Because of this, combination NRT is a good practice for all patients, to provide a baseline nicotine level with the patch and actively titrate levels using another source of nicotine replacement (18,23).

One option for a secondary source of nicotine is nicotine gum. This modality has the major advantage of satisfying oral cravings. The dosage for patients smoking fewer than 25 cigarettes per day is the 2-mg gum, and patients may chew up to 24 pieces per day. For patients smoking 25 or more cigarettes per day, the 4-mg gum is used, and patients may chew up to 24 pieces daily. Recommended duration of treatment is up to 12 weeks. Adverse effects include mouth soreness and dyspepsia. Also, it is important to remember that gum may not be socially acceptable in certain situations (18,23).

Nicotine lozenges can also satisfy oral cravings and are more socially discreet compared to gum. Dosage is based on the amount of time after patients wake up in the morning that they need their first cigarette. If patients smoke their first cigarette within 30 minutes of waking up in the morning, they should use the 4-mg nicotine lozenges. If they smoke their first cigarette more than 30 minutes after waking up, they should use the 2-mg lozenge. Patients can use between 4 and 20 lozenges per day, for up to 12 weeks. Adverse effects include hiccups, nausea, dyspepsia, and flatulence (18,23).

Nicotine inhalers, like lozenges, deliver nicotine to the bloodstream via the buccal mucosa. It also provides the user with a mechanism of delivery, with regard to hand and respiratory use, similar to that of smoking a cigarette. The inhaler comes with cartridges, each containing 10 mg of nicotine, of which 4 mg can be delivered and 2 mg is absorbed. Dosages range from 6 to 16 cartridges per day, and the patient can use the inhaler up to 6 months, with a gradual reduction in dosage. Adverse effects include irritation to the throat and mouth, and possible cough (18,23).

Nicotine nasal spray is the fastest method of delivery of nicotine into the blood system. The spray delivers 0.5 mg of nicotine in each 50-mL squirt. One dose consists of two squirts, one in each nostril. Patients can use anywhere from 8 to 40 doses per day and can use the spray for up to 6 months. Adverse effects include nasal irritation (18,23).

Varenicline

Varenicline (Chantix) is a powerful choice for treatment of smoking cessation. Varenicline is a nicotine receptor partial agonist. Acting as an agonist, it maintains moderate levels of dopamine, which help relieve withdrawal symptoms. However, acting as an antagonist, it successfully reduces the satisfaction patients feel from smoking (24). At a dose of 2 mg/day, varenicline produces the highest abstinence rate compared to any other single pharmacologic agent, with an estimated odds ratio of 3.1 compared to placebo. Dosage is 0.5 mg daily for 3 days, then 0.5 mg twice daily for 4 days, and then 1.0 mg twice daily. Treatment should be initiated 1 week before the anticipated quit date. Duration of therapy is 12 to 24 months. Side effects include nausea, vomiting, flatulence, constipation, sleep disturbance, severe angioedema, serious skin reactions, visual impairment, accidental injury, depressed mood or other psychiatric symptoms, and vivid/strange dreams. Drinking large amounts of water may ameliorate some of the side effects. Coadministration of varenicline with NRT increases the risk of adverse drug events. To prevent premature discontinuation of treatment, NRT should not be used in conjunction with

TABLE 21.3 PHARMACOTHERAPY OPTIONS FOR TOBACCO CESSATION

Pharmacotherapy	Precautions/ Contraindications	Adverse Effects	Black Box	Dosage	Duration	Availability
First-line agents						
Varenicline	Pregnancy, kidney disease, patients on dialysis, previous allergic reaction	Nausea, vomiting, flatulence, constipation, sleep disturbance, severe angioedema, serious skin reactions, visual impairment, accidental injury, depressed mood or other psychiatric symptoms, suicidal ideation, and vivid/strange dreams	■	0.5 mg/d for 3 d, then 0.5 mg twice/d for 4 d, then 1 mg twice/d. Begin treatment 1 wk before quit date	3–6 mo	Prescription only
Bupropion	Hx of seizure, hx of eating disorders, diabetics using insulin or other glycemic medication	Insomnia, dry mouth, nausea, seizures	■	150 mg every morning for 3 d, then 150 mg twice daily Begin treatment 1–2 wk prior to quit date	7–12 wk, with	Prescription only
Nicotine patch		Local skin reaction, insomnia, allergic reaction		21 mg/24 h 14 mg/24 h 7 mg/24 h or 15 mg/16 h	4 wk, then 2 wk, then 2 wk 8 wk	Prescription and over-the-counter (OTC)
Nicotine gum		Mouth soreness, dyspepsia		1–24 cigarettes/d: 2-mg gum, up to 24 pieces/d >25 cigarettes/d: 4-mg gum, up to 24 pieces/d	Up to 12 wk	OTC only
Nicotine lozenge		Hiccups, nausea, dyspepsia, flatulence		Time to 1st cigarette >30 min use 2-mg lozenge Time to 1st cigarette ≤30 min use 4-mg lozenge May use 4–20 lozenges/d	Up to 12 wk	OTC only
Nicotine inhaler		Irritation of mouth and throat, cough		6-16 cartridges per/d	6 mo	Prescription only
Nicotine nasal spray		Nasal irritation		8-40 doses/d	6 mo	Prescription only
Second-line agents						
Nortriptyline	Recent MI, concurrent or recent use of MAOI	Dry mouth, sedation, constipation, nausea	■	Start 25 mg per day, titrate up to goal of 75-100 mg/day Begin treatment 10–28 d prior to quit date	12 wk	Prescription only
Clonidine	Rebound hypertension	Dry mouth, drowsiness, dizziness, sedation, constipation, allergic reaction, bradycardia, high or low blood pressures		Transdermal: Start 0.10 mg/d, titrate up to 0.15–0.75 mg/d Oral: Start 0.10 mg twice/d, titrate up to 0.15–0.75 mg/d	3–10 wk	Prescription only

Adapted from Clinical Practice Guideline Treating Tobacco Use and Dependence 2008 Update Panel, Liaisons, and Staff. A Clinical Practice Guideline for treating tobacco use and dependence: 2008 update. A U.S. Public Health Service report. *Am J Prev Med* 2008;35(2):158–176.

varenicline. Contraindications to use include pregnancy or breast-feeding, previous hypersensitivity or skin reactions to varenicline, and patients with significant kidney disease or those who are on dialysis. There has been widespread concern regarding the increased risk of both suicidal ideation and suicide in patients on varenicline, resulting in a black box warning being placed on the medication in 2009. However, causality of these reports of self-harm and suicide are difficult to prove, as smokers have an increased baseline risk of suicide (25). Current data do not demonstrate a significantly increased risk of suicide in patients on varenicline but remain concerning due to extremely wide confidence intervals reported (26). For this reason, it is recommended to routinely observe patients for changes in behavior—including depression, suicidal ideation, or agitation—while on the medication (18,27).

Antidepressants

Sustained release bupropion is an antidepressant with dopaminergic and adrenergic actions. It also noncompetitively inhibits nicotinic acetylcholine receptors (28). In a Cochrane review examining the role of antidepressants in smoking cessation, it has been demonstrated that bupropion increases the number of successful quit attempts compared to placebo, with demonstrated quit rates around 24% (18,29). The method of action of the medication is unclear. It has been postulated that nicotine withdrawal may produce depression-like symptoms, that nicotine itself is an antidepressant and the medication simply takes the place of the action of the nicotine, or that the neural pathways and receptors modulated by the drug help break the addiction. Interestingly, the use of antidepressant medications for smoking cessation is not limited to smokers who have a previous history of depression-like symptoms. It appears that the medication works in the entire population, in those with depressive symptoms and those without (29). Recommended dosage is 150 mg every morning for 3 days and then increasing to 150 mg twice daily. The duration of therapy should last from 7 to 12 weeks and may be maintained up to 6 months. The treatment should begin 1 to 2 weeks before the anticipated quit date (18). Side effects include insomnia, dry mouth, and nausea. Rarely, it can cause seizures (29). Contraindications to use of bupropion include a history of seizures, diabetics using insulin or other glycemic medication, or a history of eating disorders (27). It is also imperative to remember that all antidepressants carry a black box warning for increased risk of suicide. When using bupropion for smoking cessation, the patient should be closely monitored for the development of behavior changes, agitation, hostility, suicidal ideation, or attempts of suicide (26).

Nortriptyline, a second-generation tricyclic antidepressant, has also been shown to increase quit rates (29). The abstinence rate of the medication compared to placebo is significantly higher, with an odds ratio of 1.9 (18). It has been proposed that the medication acts by inhibition of the reuptake of serotonin and noradrenalin. Recommended dosage is initially 25 mg/day, gradually increasing to a goal of 75 to 100 mg/day for a treatment period of 12 weeks. The treatment should also be initiated 10 to 28 days before the target quit date. Side effects include dry mouth, sedation, constipation, and nausea. Contraindications for use include a recent myocardial infarction (MI), or the concurrent or recent use of monoamine oxidase inhibitors (MAOIs). There is also a potentiating effect when combined with alcohol, and overdose can lead to numerous dangers (29,30). Of note, the FDA has not yet approved this medication for smoking cessation.

Not all antidepressants help with smoking cessation. Selective serotonin reuptake inhibitors (SSRIs) and MAOIs are not effective medications in smoking cessation. In a Cochrane review, SSRIs demonstrated the same effectiveness in smoking cessation as a placebo (18,29).

Other Medications

Clonidine, an alpha-2-noradrenergic agonist, has also been shown to increase the rate of smoking cessation, with an odds ratio of 2.1 compared to placebo (18). Dosage starts at 0.10 mg twice per day orally or at 0.10 mg/day using a transdermal patch. Dosing is then increased if needed by 0.10 mg/day to a final dosage of 0.15 to 0.75 mg/day. Duration of treatment is 3 to 10 weeks. Adverse effects include dry mouth, drowsiness, dizziness, sedation, and constipation. Contraindications include rebound hypertension. It is also critical to be aware of the potential for allergic reactions, bradycardia, or extremely high or low blood pressures (30). The FDA has not approved this medication for smoking cessation.

Naltrexone, an opioid receptor antagonist, does not have a role in smoking cessation. In fact, when compared to a placebo, it was found to be less effective (18).

Pharmacotherapy Conclusions

There are many viable options for pharmacotherapy (Table 21.4). At a dose of 2 mg/day, varenicline produces the highest abstinence rate compared to any other single pharmacologic agent. However, single modality pharmacotherapy is not the rule. Combination therapies can also offer excellent abstinence rates. Combining the nicotine patch with a second medication can achieve slightly higher rates of abstinence compared to using the patch alone. The patch can be combined with another form of ad lib nicotine replacement (gum, inhaler, lozenge, or spray), and/or it could be added to bupropion, nortriptyline, or clonidine. In all these combinations, it has been demonstrated there is likely a slight increase in abstinence rates compared to the use of a single medication alone. However, it is important to remember that varenicline should not be combined

TABLE 21.4 EFFECTIVENESS AND ABSTINENCE RATES OF PHARMACOTHERAPY FOR SMOKING CESSATION COMPARED TO PLACEBO

Medication	Estimated OR (95% CI)	Estimated Abstinence Rate (95% CI)
Nicotine patch + ad lib NRT (gum or spray)	3.6 (2.5, 5.2)	36.5 (28.6, 45.3)
Varenicline (2 mg/d)	3.1 (2.5, 3.8)	33.2 (28.9, 37.8)
Nicotine patch + bupropion SR	2.5 (1.9, 3.4)	28.9 (23.5, 35.1)
Nicotine nasal spray	2.3 (1.7, 3.0)	26.7 (21.5, 32.7)
Long-term nicotine gum (<14 wk)	2.2 (1.5, 3.2)	26.1 (19.7, 33.6)
Nicotine inhaler	2.1 (1.5, 2.9)	24.8 (19.1, 31.6)
Clonidine	2.1 (1.2, 3.7)	25.0 (15.7, 37.3)
Bupropion SR	2.0 (1.8, 2.2)	24.2 (22.2, 26.4)
Nicotine patch	1.9 (1.7, 2.2)	23.4 (21.3, 25.8)
Nortriptyline	1.8 (1.6, 2.6)	22.5 (16.8, 29.4)
Nicotine gum (6–14 wk)	1.5 (1.2, 1.7)	19.0 (16.5, 21.9)
Placebo	1	13.8
Selective serotonin reuptake inhibitors	1.0 (0.7, 1.4)	13.7 (10.2, 18.0)
Naltrexone	0.5 (0.2, 1.2)	7.3 (3.1, 16.2)

with nicotine replacement due to the pharmacodynamics of the drug (18).

CESSATION PROGRAMS AND RESOURCES

Quitlines

Telephone quitlines exist in every state. In fact, these quitlines have been found to be effective methods of treating nicotine dependence. In a recent meta-analysis, not only were quitlines found to produce significantly higher cessation rates compared to individuals who had not undergone counseling, but when combined with medications, they were also found to offer significantly better results compared to patients using pharmacotherapy alone (21). These data suggest that quitlines represent another form of intervention that can be utilized in multimodality therapy. These services can be accessed by calling either 1-800-QUIT-NOW or 1-877-2NO-FUME. The National Cancer Institute of the National Institute of Health also sponsors a quitline, 1-800-44U-Quit. These lines offer free counseling and are able to get patients in contact with other local programs.

Online Resources

The World Wide Web is another excellent supplemental resource as there are many online tools available for both patients and health care professionals.

- For health professionals
  - US Department of Health and Human Services Cessation Guidelines site contains the most definitive literature on tobacco cessation. http://www.surgeongeneral.gov/tobacco/default.htm

SMOKING CESSATION FOR THE SURGEON—PERIOPERATIVE CONSIDERATIONS

The effects of smoking are important to consider in the perioperative period as smokers have an increased risk of intraoperative and postoperative complications. These risks are due to the added stress placed on the cardiac and pulmonary systems as well as complications with wound healing.

Perioperative myocardial infarctions are caused by either acute coronary thrombosis or supply–demand mismatches in the setting of critical coronary stenosis (31). Unfortunately, both the cardiac and circulatory systems are damaged by smoking—specifically by the development of atherosclerosis. Also, in the smoker who has recently smoked, nicotine and carbon monoxide are present and work to cause a mismatch in the amount of oxygen availability compared to the rate of consumption. The presence of nicotine stimulates the cardiovascular system, increasing oxygen demand (20). However, carbon monoxide reduces the availability of oxygen to tissues by reconfiguring the structure of hemoglobin resulting in a decreased affinity for binding oxygen and also by acting as a competitive inhibitor to oxygen (32).

The pulmonary system is also negatively impacted by smoking. This is in part due to the fact that smoking leads to lung disease such as chronic obstructive pulmonary disease. It also leads to an increased risk of complications in the perioperative period. In fact, smokers have approximately six times the risk of developing postoperative complications compared to nonsmokers (33). Increased mucus production in combination with decreased ciliary movement leaves the airway at increased risk. Also, smoking impairs pulmonary immune function (20,34).

Smoking also is associated with complications with surgical wound healing, primarily due to hypoxia related to reduction of blood flow, decreased oxygen carrying capacity, and peripheral vasoconstriction. Hypoxia also limits the ability of tissue to repair itself and also leads to increased susceptibility to infection. Also, smoking may inhibit fibroblasts, interfere with angiogenesis, and significantly reduce peripheral microcirculation (35–37).

Smoking cessation in the perioperative period can help prevent these postoperative complications. Optimal risk control is obtained by helping the patient quit smoking 1 to 2 months before surgery, incorporating the cessation methods outlined previously in this chapter. This results in significantly lower complication rates and also obtains the highest short-term and long-term quit rates (20,38). However, if this is not possible due to time constraints, it has also been demonstrated that simply stopping 4 weeks before surgery does decrease overall complication rates (39). In fact, in patients undergoing cancer resection with free flap reconstruction, it was determined that preoperative smoking cessation longer than 3 weeks prior to surgery significantly reduced the wound healing complications (40). With this in mind, every attempt should be made to achieve smoking cessation in the preoperative period. While it is not clear exactly what is the shortest duration of preoperative abstinence from smoking needed to reduce perioperative complications, it is clear that a longer duration is better—specifically 1 to 2 months—and that long-term quit rates are best achieved with the addition of intensive counseling and pharmacotherapy.

The optimal timing for smoking cessation in the perioperative period specifically with respect to pulmonary complications remains perplexing. Investigations have revealed mixed results, with some noting that patients are at a decreased risk by stopping smoking before surgery, while others have noted a higher risk of pulmonary complications by stopping smoking in the immediate preoperative period. In fact, some publications found that stopping smoking before an operation can result in a rate of pulmonary complications up to seven times the normal rate (33). However, it does seem clear that the closer to surgery the patient ceases smoking, the higher the risk that the patient has of pulmonary complications. One thought is that the increased mucus production that occurs after cessation plays a role in this process. In any case, the overall rate of complications is decreased with smoking cessation no matter how close to surgery it is initiated, so this should not be a reason to continue smoking (34).

NRT is one of the cornerstones of pharmacotherapy for smoking cessation. With this in mind, it is important to consider the effects of NRT on the surgical patient. Smoking has been found to reduce tissue blood flow to tissues, reduce oxygen levels, and significantly negatively impact aerobic metabolism. It was previously assumed that these effects were due to nicotine. Though nicotine can cause vasoconstriction and has been shown to decrease surgical flap survival in animal experiments, these effects occurred at much higher doses than seen with smoking or NRT (41).

Recent work found that administration of IV nicotine resulted in a significant increase in tissue oxygen levels, with only a limited vasoactive effect and no change in the aerobic metabolism of the tissue (35). This is in sharp contrast to the effects of smoking. It has also been suggested that nicotine stimulates dermal cells and promotes angiogenesis (42). In another study, when administered at therapeutic levels, transdermal nicotine had no effect on digital perfusion compared to individuals who had just stopped smoking. Also, microvascular responses were similar to that of the control group of nonsmokers (43). In another population, the use of NRT starting 6 to 8 weeks before surgery has demonstrated dramatic reductions in both the overall complication rates and wound complication rates in patients undergoing hip or knee replacement (44). Also, NRT does not increase the perioperative cardiac risk (41).

With these studies in mind, nicotine replacement may not result in the complications that we have historically attributed it to. At this point, nicotine use in the perioperative period has not been fully investigated, although current evidence suggests it does not significantly impair wound healing after surgery.

CONCLUSIONS

Tobacco abuse represents a chronic disease that is regularly encountered by the otolaryngologist. It impacts our practice in a variety of ways, contributing to the development of many disease processes, and impedes our ability to deliver excellent surgical outcomes. With this in mind,

it is imperative that every otolaryngologist includes a systems-based tobacco cessation program that allows for the identification of tobacco users and facilitates the initiation of a multimodality approach to cessation. This approach should include intensive counseling, pharmacotherapy using multiple medications, access to support and counseling networks—including quitlines and Web-based resources, and close follow-up. Comprehensive smoking cessation programs have been shown to have a significant impact on patients' long-term success rates and should be offered to every tobacco-dependent patient.

HIGHLIGHTS

- Tobacco dependence is a chronic disease, and it is extremely difficult to overcome addiction to nicotine.
- There are effective treatments for tobacco cessation.
- Clinicians must consistently identify and document tobacco use and perform the brief clinical intervention—the 5As—on every tobacco user.
- Multimodality treatment includes counseling, pharmacotherapy using multiple medications, access to support and counseling networks including quitlines and Web-based resources, and close follow-up.
- Intensive weekly counseling sessions should be conducted for a period of 4 to 8 weeks.
- Pharmacotherapy should consist of either varenicline or a long-acting nicotine patch in combination with an additional source for acute nicotine replacement and, optionally, the addition of an antidepressant.
- For patients not ready to quit, motivational interview techniques should be employed.
- Efforts directed toward tobacco cessation are among the most important things we can do for our patients.
- NRT does not result in tissue hypoxia and should be offered to patients in the weeks before surgery.

22 Palliative Care and Pain Management

Robert M. Taylor *Amit Agrawal*

Palliative care (PC) is a holistic approach to medical care for patients with serious illness that focuses on optimizing comfort and quality of life (QOL) for patients and their families. The Report of the National Consensus Project (NCP) Clinical Practice Guidelines for Quality Palliative Care states: "The goal of PC is to prevent and relieve suffering and to support the best possible QOL for patients and their families, regardless of the stage of the disease or the need for other therapies. PC is both a philosophy of care and an organized, highly structured system for delivering care. PC expands traditional disease-model medical treatments to include the goals of enhancing QOL for patient and family, optimizing function, helping with decision making, and providing opportunities for personal growth. As such, it can be delivered concurrently with life-prolonging care or as the main focus of care" (1). As such, PC is appropriate for many patients with head and neck cancer (HNC), even those who may be cured of their cancer, but suffer significant symptoms and/or functional impairments, as well as the risk of recurrence.

Indeed, patients with HNC represent an important and challenging population for modern medicine. Although new therapies have significantly improved life expectancy and survival for patients with HNC, many patients who benefit from these treatments are left with significant problems as a result of their cancer and therapy, including pain, dysphagia, dysarthria, disfigurement, and psychological sequelae. Family and social problems may be significant. Because addiction to alcohol is a risk factor for HNC, and because many alcoholics abuse other substances, addiction and substance abuse may further complicate the patient's struggles and the medical system's ability to provide care.

Ideally, treatment of patients with HNC should include a collaboration of surgery, medical oncology, radiation oncology, speech therapy, nutrition, and a PC team. PC teams often include professionals from medicine, nursing, social work, chaplaincy, pharmacy, and other professional disciplines. Among the other disciplines that may provide additional important support for HNC patients are psychology and addictionology.

One of the priorities of those working in the field of PC is to encourage incorporation of PC into the earlier phases of cancer treatment, often referred to as moving PC "upstream." This priority is based on the reality that PC is much more than end-of-life (EOL) care and provides important benefits for patients with cancer during the earlier phases of their illness. PC must be distinguished from hospice care, which is appropriate for, and limited to, patients who are estimated to have 6 months or less to live (assuming their disease runs its expected course). Although hospice is an important component of PC, PC is a much broader enterprise that is appropriate for patients at any stage in a serious illness, such as cancer. Furthermore, although comprehensive PC is best provided by an interdisciplinary PC team, the principles of PC can often be integrated into the care of cancer patients by non-PC clinicians.

PRESENTING SYMPTOMS AND ASSESSMENT OF PATIENTS WITH HNC

While presenting symptoms and level of dysfunction caused by early stages of HNC are typically less severe, it is extremely common in patients presenting with advanced-stage primary or recurrent disease to experience significant and often debilitating symptoms caused either directly or indirectly by their tumor. Although variable according to tumor type and location, progressive pain is an extremely common symptom particularly in patients presenting with advanced and/or recurrent disease (2–4). Pain in patients with advanced disease may be due to one or multiple factors (5,6) including extensive soft tissue and/or bony

infiltration, direct perineural involvement by tumor, and/or disease affecting substantial portions of exposed mucosal surfaces resulting in local ulceration/irritation. As such, pain caused by cancer or its treatment is felt to be mediated by neuropathic and/or local inflammatory mechanisms (7) and may be associated with systemic inflammation as well (8). Pain causes not only physical distress and dysfunction, but significant psychological effects with negative impact upon overall QOL (3). Unfortunately, underassessment of severity of pain as well as factors involving physician discomfort, lack of understanding pain mechanisms and thus strategies necessary to achieve sufficient symptom relief, lack of recognition of important coexisting psychological factors such as depression, as well as concerns regarding potential for addiction or substance abuse often lead to undertreatment of pain in patients affected by this disease. It is thus important for physicians and healthcare providers to both become knowledgeable in basic tenets involved in oncology pain management as well as to regularly involve healthcare providers with specific expertise in pain and PC in order to maximally benefit patients and minimize suffering due to such symptoms.

Progressive disease bulk due to disease location in the upper aerodigestive tract and/or neck can also result in severe functional compromise by interfering with vital functions including eating, swallowing, and respiration which may require more urgent intervention independent of disease status. Assessment by the head and neck surgeon and/or oncologist is necessary to determine both oncologic course as well as to guide management of existing or potential tumor and/or treatment-related complications (airway compromise, dysphagia, bleeding, infection) including consideration of whether patients may benefit from adjunctive interventions such as tracheostomy or feeding tube placement. Such interventions must be discussed with patients as to their impact which although may extend longevity are not likely to be temporary measures in patients with recurrent and often incurable disease.

Not uncommonly, particularly in cases of advanced disease, troublesome bleeding occurs due to friability and vascularity of exposed tumor surfaces which can be a source of significant distress to both patients and caregivers. In mild cases, it is reasonable to employ local measures such as application of direct pressure, use of topical hemostatic agents, coagulation, and wound care (e.g., measures to maintain moisture and reduce bacterial load). In recalcitrant cases, interventional radiologic procedures such as endovascular tumor embolization can be considered to control recurrent bleeding (9,10). In the dire situation of threatened, impending, or actual severe sudden bleeding resulting from exposure, erosion, or compromise of major vascular structures (e.g., carotid blowout), depending upon the acuity and stability of the patient, consideration can be given to intervention such as endovascular carotid stenting, occlusion, or open carotid artery ligation which often achieves immediate stabilization and control of bleeding (11,12). It must be realized, however, that such measures are considered extreme and although potentially lifesaving in the short term are associated with high morbidity (e.g., stroke) with dubious impact upon QOL and overall survival. As such, in patients recognized to be at risk of such events (previously treated patient with recurrent neck disease in setting of open neck and/or pharyngeal wound), this potential event should be discussed with patients and families and the patient's wishes ascertained including the use of aggressive resuscitation measures, which may not be desired particularly when the goals of care remain primarily palliative.

Due to the significant and variable presentation of advanced head and neck malignancy, whether primary or recurrent, patients require assessment often in multidisciplinary fashion in order to address the oncologic as well as functional, and symptomatic aspects of their disease. Although there may be some overlap, involvement of caregivers in the areas of oncology, pain and PC, speech/swallowing, nutrition, mental health, and nursing play crucial roles in the management of patients with HNC.

PALLIATIVE ANTINEOPLASTIC THERAPIES

In the setting of advanced head and neck malignancy in which standard curative intent therapy is not felt feasible, it is still not unreasonable to consider antineoplastic strategies in an effort to achieve reduction in tumor burden as this has been shown to achieve meaningful palliation of debilitating symptoms such as pain, swelling, and dysphagia (13,14). Although more difficult to measure, additional factors potentially improved by such efforts also include reduction in tumor-related complications such as bleeding or impingement upon local vital functions such as airway. Such strategies include palliative use of chemotherapy/systemic therapy, radiotherapy, and surgery. The use and selection of such modalities alone or in combination often depend upon factors such as patient functional status, prior therapy, as well as practical feasibility and expected functional morbidity associated with such measures.

Chemotherapy

It has been shown that systemic therapy can be expected to achieve meaningful response and thus reduction in tumor burden ranging from 10% to 30% of cases of advanced recurrent disease when patients have undergone significant prior therapy although the effect of therapy is temporary (median time to progression 6 months, survival <12 months) (15–17). Higher rates of disease response can be achieved with combination of more than one systemic agent compared to monotherapy, although such response typically occurs at the expense of higher toxicity and morbidity either without substantial improvement or only modest improvement in overall survival (15,16).

Such impact may not be desirable when the intent of therapy is symptom palliation particularly in situations where declining patient functional status may preclude aggressive measures. As such, it is not unreasonable to utilize systemic monotherapy in such situations, although multiagent therapy should be considered particularly when patients possess good performance status as there is some evidence that multiagent therapy can achieve improvement in specific parameters such as pain and swallowing without negatively impacting overall global QOL measures (14). Commonly utilized systemic agents used either as monotherapy or in combination include methotrexate, platinum compounds (cisplatinum, carboplatinum), 5-fluorouracil, taxanes (paclitaxel, docetaxel), as well as in recent years targeted therapy strategies using agents such as cetuximab which target the epidermal growth factor receptor pathway. Although symptomatic benefit is more likely in patients who achieve measurable disease response to therapy, interestingly, symptomatic improvement can also be observed despite absence of overt response to treatment albeit in a smaller proportion of patients (13).

Radiation Therapy

In the setting of advanced recurrent locoregional disease, the use of radiotherapy in palliative format can be considered, although in most cases of advanced recurrent disease, prior radiotherapy in affected regions may preclude its use. The use of reirradiation has been utilized in situations in an effort to reduce tumor burden and achieve disease response with variable success using varying methodology involving standard fractionated, altered fractionated, stereotactic/conformal delivery, or brachytherapy delivery methods (18–22). It must be understood that even with altered delivery methods reirradiation alone is associated with low overall response rates and disease control in previously treated regions. Furthermore, despite demonstrated feasibility, the rate of severe treatment-related toxicity (i.e., grade 3 or greater) of reirradiation is significant (21,22). As such, in light of the low rate of observed disease response and significant treatment toxicity, the role of palliative reirradiation in achieving meaningful symptom relief in patients with otherwise incurable recurrent HNC remains unclear (21).

The use of reirradiation in combination with systemic chemotherapy (with or without surgery) has also been utilized in patients with advanced locoregional recurrence with sustained disease response documented in a small but significant proportion of patients (23–25). It must be understood, however, that long-term survival in this patient group remains low, and the morbidity and mortality associated with such measures are not small (23–25). Furthermore, the intent of such treatment should be considered definitive in nature, and as such, it would be difficult to categorize such treatment as palliative in intent. In situations of distant disease such as bony or central nervous system (CNS) metastases, it is reasonable to consider palliative radiotherapy to these sites in situations of severe symptoms or high potential for debility from disease (e.g., bone pain, impingement upon spinal cord/CNS) (26).

Surgery

The use of surgery to reduce tumor burden in palliative fashion when meaningful chance of cure does not exist is controversial. In the situation of advanced recurrent head and neck malignancy, surgery is often not feasible or practical due to disease extent (i.e., unresectable) or patient factors (medical debility, poor nutritional/performance status). Even if feasible, surgery often carries substantial morbidity with high risk of postsurgical wound complications and substantial potential for negative impact upon functions including speech, swallowing, and respiration and as such is frequently associated with need for adjunctive devices such as tracheostomy and/or feeding tube which may be either at least temporary or may be long term or permanent in a significant proportion of patients (27). Furthermore, in patients previously treated for advanced disease, surgery for recurrent disease is associated with low chance of long-term disease control (27,28). As such, the benefit of surgical measures must always be carefully weighed against the potential substantial negative impact upon function and QOL particularly when odds of meaningful disease control are low and treatment intent is palliative. It is not unreasonable however to consider surgical efforts—even aggressive efforts—in situations where symptoms, QOL, and longevity are primarily impacted by locoregional disease provided that disease is felt to be reasonably addressed using surgery (with or without further adjuvant measures) and potential for recovery of function is substantial (i.e., via reconstruction and/or rehabilitative methods). It is also reasonable to consider palliative surgical measures in situations where distant disease may exist yet have indolent behavior provided that locoregional disease can be controlled where other methods such as chemotherapy and/or radiotherapy carry poor odds of reducing locoregional disease burden (e.g., adenoid cystic carcinoma, well-differentiated thyroid cancer). Such considerations must be taken in concert with careful surgeon assessment of the feasibility and functional impact of surgical treatment and honest discussion with patients and families regarding realistic expectations of any such proposed measures particularly with regard to symptom control and QOL.

PALLIATIVE CARE CLINICAL PRACTICE GUIDELINES

The number of hospital-based PC programs more than doubled between 2000 and 2009, according to study done by the Center to Advance Palliative Care (29). In 2009, the NCP published updated Practice Guidelines (1)

"to promote quality and reduce variation in new and existing programs, develop and encourage continuity of care across settings, and facilitate collaborative partnerships among PC programs, community hospices, and a wide range of other health care delivery settings." In their effort to promote a holistic view of PC as well as to encourage appropriate clinical standards, they identified eight essential domains of PC:

1. **Structure and processes of care**: This domain emphasizes the importance of ensuring that adequate resources and personnel are available to provide holistic care for patients with serious illness. Ideally a well-resourced and staffed PC team should be available to assist with the care of patients with significant PC needs, and their families. Most patients will be receiving significant assistance and support from their family (broadly defined) and want their family involved in any important decisions. Some patients will be very selective as to which family members they want involved. Rarely, patients will not want anyone else involved in their care; while their wishes should be respected, treatment options will likely be limited by a lack of support from others. Treatment options will, of course, also be limited for patients who have no family assistance. Eliciting patient—and, if appropriate, family—values and goals is a necessary step in providing optimal care. Likewise, coordinating care among the many providers is essential. Furthermore, understanding and accessing available resources in the hospital and community, such as mental health services, cancer-specific resources, support for children, home health services, and hospices, is critical to ensure that patients and families receive the care they need.
2. **Physical aspects of care**: All patients with cancer should be provided with the best available management of pain and other physical symptoms. All physicians who treat cancer should understand and apply the basic principles of managing pain and other physical symptoms to minimize unnecessary suffering by their patients. They should be skillful at eliciting and recognizing sources of physical distress and know the limits of their own ability to manage such problems. They should be aware of options for patient referral for pain and symptom management and be prepared to advocate for and support the development of PC services within their own institutions to ensure that their patients' physical distress is addressed appropriately.
3. **Psychosocial and psychiatric aspects of care**: Patients with cancer typically suffer significant psychological distress. This may include depression and anxiety related to their disease and associated physical symptoms and debilitation, losses resulting from the disease—such as loss of employment, income, or relationships, concerns about one's ability to fulfill one's responsibilities, etc. If the patient has a preexisting mental illness, addiction, or cognitive impairment, their ability to cope with cancer may be significantly diminished. All cancer patients should be assessed for such problems, ideally by a trained professional, such as a social worker or psychologist. Resources and personnel to evaluate and manage such common problems should be available to all those who treat cancer patients. Some patients may require referral for specialized care, such as a psychiatrist or a substance-abuse program. Finally, families of patients who die should have access to grief and bereavement services and clinicians should be capable of assessing the need for such services.
4. **Social aspects of care**: Patients with cancer live and struggle within families and communities. Although families provide critical support for many cancer patients, all families suffer along with the patient and, for some patients, families may be an additional source of stress—due to complexity of family structure, dysfunctional relationships, or inability to fulfill one's historical responsibilities within the family. Other concerns include the family's ability to fulfill caregiver needs for the patient; when families are unable, other resources may or may not be available, depending on a variety of factors. A patient's and family's access to resources in the community may vary considerably, based on their socioeconomic and insurance status, as well as integration into their community, for example through work, friendships, or church. Inadequate social support may interfere with a patient's ability to comply with treatment recommendations and have a negative impact on outcomes. Identifying and addressing the social needs of patients and families is best accomplished with the help of an interdisciplinary team, including social workers experienced in the care of patients with cancer.
5. **Spiritual, religious, and existential aspects of care**: Patients with serious illness inevitably confront spiritual and existential issues. Spirituality is usually conceptualized as encompassing the patient's sense of meaning and purpose, his or her connectedness to self, family, friends, and community, the significance of suffering, and a possible connection to a higher power. Existential issues are the result of one's encounter with one's own mortality and the reality of nonexistence in this world. As such, all patients, on some level, struggle with spiritual and existential concerns, whether they identify them as spiritual or not. For many patients, religious beliefs, communities, and traditions will influence how they understand and cope with their illness. Other related spiritual issues include life review, assessment of hopes and fears, a sense of guilt and forgiveness, and life-completion tasks. All patients with cancer should be assessed for spiritual, existential, and religious concerns. Spiritual and religious concerns may take on added significance for patients approaching the

EOL. Often, spiritual assessment and care is provided through pastoral care, although other members of the health care team, including physicians, may be able to perform a spiritual assessment. Resources for providing spiritual care include the hospital chaplain, other members of a PC team, and community resources, especially—if a patient has one—the patient's own faith community. A useful spiritual screening tool is the acronym FICA, where each letter stands for a word which prompts certain questions:

a. **Faith**—Do you consider yourself spiritual or religious? Do you have spiritual beliefs that help you cope with stress? What gives your life meaning?
b. **Importance or Influence**—What importance does your faith or belief have in your life? Have your beliefs influenced how you take care of yourself in this illness? What role do your beliefs play in regaining your health?
c. **Community**—Are you a part of a spiritual or religious community? Is this of support to you and how? Is there a group of people you really love or who are important to you?
d. **Address or Apply**—How would you like me, your health care provider, to address these issues in your health care?

6. **Cultural aspects of care**: Many patients are influenced by the beliefs and traditions of their community, ethnicity, or religion. For example, one's culture may affect patterns of communication and decision making within the family, as well as the significance of illness in the patient's worldview, or even one's understandings of the mechanisms of disease. Communication may be hindered by language differences. Simple considerations such as diet and activity may be influenced by cultural concerns. Preferences related to EOL care, including especially the ritual aspect of care, as well as the handling of the body after death, may be influenced by cultural considerations. However, because a patient's and family's sense of cultural identity is complex and unpredictable, it is important to elicit their perspective and its significance in a culturally sensitive manner. Social workers and pastoral care are often the most skilled in eliciting cultural perspectives and concerns.
7. **Care of the imminently dying patient**: A patient who is imminently dying is in a specific and unique condition that is fundamentally different from the condition of other seriously ill patients. Properly caring for an imminently dying patient requires appreciation of this reality and specific knowledge and skills, which, unfortunately, have not been widely taught to medical trainees in the past. Medical care is ordinarily provided for patients based on the assumption that the goal is to help them survive and, ideally, be restored to health. As such, many "routine" and "standard" treatments, such as respiratory support or artificial hydration and nutrition (AHN), serve to maintain survival while more specific treatments are applied to treat an illness or injury. However these "routine" treatments may provide no benefit, or even cause harm, to a patient who is actively dying. For example, dying patients, whose organs are progressively and irreversibly failing, are unable to effectively process and utilize AHN and often develop respiratory distress due to pulmonary edema if AHN is continued during the dying phase. Understanding and explaining this effectively and compassionately to families is critical to providing optimal care to imminently dying patients. Although it is not always easy to determine when a patient has entered the dying process, it usually becomes evident to experienced clinicians sometime before the patient dies. Furthermore, recognition that the patient's death is probable, or even inevitable, is often apparent well before he or she is imminently dying. When a patient is recognized to be imminently dying, two goals should become primary: to strive to ensure the comfort of the patient (based on best medical evidence, within ethical and legal guidelines) and to provide support for the family and significant others. Ideally, a hospice or a PC program should provide such care, as those programs are best able to achieve both goals. Delaying referral to hospice or PC until the patient is imminently dying may result in suboptimal care for the patient and family. EOL care for patients with HNC is discussed in more detail below.
8. **Ethical and legal aspects of care**: Physicians should ensure that patients are adequately informed about their treatment options and elicit their goals and preferences. Patients should be encouraged to complete advance directives, so that they have the opportunity to appoint a surrogate decision maker and inform the physician and surrogate of their preferences regarding EOL care. Advance care planning should be presented to patients as an opportunity to ensure that their preferences are honored if they ever lose the capacity to make their own decisions. If a patient does lose the capacity to make decisions, ethical and legal guidelines should be followed to ensure that the decisions regarding the patient's care are made appropriately. Most conflicts or uncertainties in EOL care can be resolved through compassionate communication. It is often helpful to have such conversations facilitated by experienced PC physicians. However, in cases where conflict persists, an ethics consult may be helpful.

PAIN IN HEAD AND NECK CANCER

The International Association for the Study of Pain (IASP) defines pain as "an unpleasant sensory and emotional experience associated with actual or potential tissue damage or described in terms of such damage" (30). Pain is always subjective, and consists of a physiologic and a psychological component, both of which can alter the perceived severity and the level of distress resulting from pain.

Acute pain in HNC is often associated with therapeutic interventions, for example acute postoperative pain. Such pain is typically managed with short-term intravenous opioid therapy in the acute-care setting. Although management of acute pain can certainly be challenging and problematic, the predominant challenge in managing cancer-related pain relates to the management of chronic pain. Therefore, the focus of this discussion is on chronic pain in HNC.

In cancer pain, the etiology and mechanism of the physiologic component of the pain is often apparent, or can be inferred, based on the history, exam, and imaging studies. However, the distress caused by pain may be greatly influenced by a multitude of other factors, including psychological, social, and spiritual factors. Furthermore, cancer pain is often perceived as indicating persistent, progressive, or recurrent disease; whether it turns out to be correct or incorrect, this perception frequently further increases distress. Indeed, reassurance that the pain does not reflect active cancer may be very therapeutic (31).

Pain in HNC can occur as a result of the disease itself or therapy. HNC may cause somatic pain by invasion and destruction of soft tissues and bone, it may cause neuropathic pain (NP) by invasion or destruction of nerves of the head and neck, or it may cause mixed pain (a combination of somatic pain and NP). Similarly, treatment may cause pain by similar mechanisms as well as additional mechanisms. Radiation therapy (RT) may cause mucositis, xerostomia, fibrosis, and radionecrosis. Pain related to HNC, or its treatment, most often involves the head, neck, shoulder, and arm. However, certain chemotherapy regimens may be neurotoxic and cause painful polyneuropathies unrelated to the specific cancer site. Pain may resolve with treatment or subsequently, or may be persistent. Persistent pain may or may not reflect persistent disease. Recurrent pain or progressive pain frequently reflects recurrent or progressive disease (32). The impact of pain on psychological distress, sense of well-being, and QOL is complex and is discussed below.

There are few studies documenting the incidence and prevalence of pain in HNC and many of these were performed several years ago. Although subsequent changes in treatment regimens create uncertainty as to the applicability of these studies to current patients, the data they provide remain among the best available at this time.

One recent prospective study, published in 2009, assessed pain over a 3-month period, in HNC patients undergoing RT who reported pain on initial evaluation (33). Seventeen percent were treated with only RT, 57% were treated with surgery and RT, 14% with chemotherapy and RT, and 11% with all three modalities. On a "0-5 verbal pain descriptor scale," worst pain was 3.03 at first visit, 3.18 at second visit, and decreased at subsequent time points. Continuous pain was reported by 57%, and combined continuous and intermittent pain by 79%. Although they did not report the percentages of patients reporting neuropathic, nociceptive, or mixed pain, the most common NP descriptors endorsed were burning (27%) and aching (20%); nociceptive descriptors were tender (35%), sore (32%), throbbing (23%), and dull (22%); and affective/evaluative descriptors were annoying (41%) and tiring (25%). Overall, 29% were not satisfied with their level of pain.

A 2-year, prospective, longitudinal study published in 1999, assessed pain, life satisfaction, and psychological distress, in 93 of 201 patients treated for HNC who remained disease free at the end of the study (34). Head and neck pain (HNP) were reported by 48% of patients at presentation and by 25% and 26% at 1 and 2 years, respectively. Moderate to severe HNP was reported by 27% at presentation, and 10% and 15% at 1 and 2 years, respectively. Shoulder and arm pain (SAP) were reported by 14% at presentation, and 37% and 26% at 1 and 2 years, respectively. Moderate to severe SAP was reported by 3% at presentation, and 18% and 14% at 1 and 2 years, respectively. There was no significant difference in pain experienced by those treated with surgery, radiation, or both. However, neck dissection was significantly associated with SAP at 2 years. Life satisfaction was adversely affected by any pain at 1 and 2 years, whereas psychological distress was only associated with pain at 3 months.

Despite the quality of this study, there are several reasons that it may be of limited applicability to current HNC patients. First, treatment regimens for HNC have changed; for example, none of the patients in the study were treated with chemotherapy. Second, as it was an observational study; pain management was neither provided nor assessed. Nevertheless, the authors report that "it became clear … that their pain was generally unreported to their doctor and was self-medicated." Finally, because they included only patients who remained disease free at 2 years, their results are of limited applicability to patients with residual, recurrent, or advanced disease.

A prospective study of pain in 167 patients with HNC, published in 1993, may be more widely applicable to patients with HNC, as they included patients with all stages of disease and included information about treatment (35). They found that 83% had pain related to cancer and 28% related to treatment. Systemic analgesics were administered to 97% of patients and adjuvants to 100%; 5% of patients reported severe pain despite treatment. The most common side effects of pain treatment were insomnia, dysphagia, anorexia, constipation, and nausea; serious side effects were rare.

A prospective study of 2,266 cancer patients referred to a pain service, published in 1996 provided a different perspective on pain in HNC (36). All patients had pain; 17% had HNC. Pain in HNC patients was most common in head, face, and mouth (78%) and cervical region (45%); 9% had pain in the shoulder or upper limb and 7% in the thoracic region. 81% had disease-related pain, whereas 31% had treatment-related pain. NP was diagnosed in 25% of the former and 45% of the latter.

The combined results of these studies suggest a few conclusions:

1. The majority of patients with HNC will have pain, which may be difficult to treat. Pain may be somatic, neuropathic, or mixed.
2. Up to a quarter of patients who remain disease free at 2 years may have persistent pain, which may be moderate to severe in up to 15%.
3. Persistent SAP is associated with neck dissection.
4. Of the HNC patients who seek treatment for pain, the most common sites of pain are the head, face, mouth, and neck.

Principles of Pain Assessment and Management

The principles of pain management for cancer patients are well described in multiple sources. For example, The National Cancer Institute's Physician Data Query Web site provides a brief overview of the principles of cancer pain management (37), *The Oxford textbook of palliative medicine* devotes several chapters to this topic (38), and Portenoy (39) recently provided a concise review of this topic. This discussion attempts to apply those principles to the HNC population. Although pain management may be a significant consideration for head and neck patients with nonmalignant syndromes involving the head and neck, it is especially important for patients with HNC. Furthermore, although the principles of pain management for HNC are generally applicable to patients with nonmalignant syndromes, the ethical and legal considerations are more complex for the latter group of patients. Specifically, although concerns about misuse or abuse of medications, addiction, and diversion are always important in every patient population, with nonmalignant disease, there is a stronger legal and ethical requirement to monitor for and manage these problems. In addition, as in any nonmalignant pain syndrome, there must always be a strong focus on monitoring and improving functional status, as a decline in functional status may often indicate misuse, abuse, or addiction. In contrast, this may not be as relevant to the care of patients with malignant disease, who may have a decline in functional status due to disease progression, even while receiving optimal pain management. Nevertheless, decline in functional status of HNC patients that is not associated with disease progression should raise concern about medication misuse, abuse, or addiction.

Portenoy (39) offers a summary of "Key messages" that should inform the management of cancer pain; these are reproduced in Table 22.1.

The first step in treating pain is to determine the etiology of the pain and the mechanism of the pain. In patients with HNC, the mechanism of the pain is often easily

TABLE 22.1 KEY MESSAGES

- The assessment and management of pain in populations with cancer are best considered as an essential component of the broad therapeutic approach known as Palliative Care
- Pain assessment should characterize the pain complaint, take into account the status of the underlying disease, clarify the pain in terms of its cause, syndrome, and pathophysiology, and obtain details about other factors that contribute to illness burden
- Pain can be addressed with primary disease-modifying treatment, most often radiotherapy, if this approach is available, feasible, and consistent with the goals of care
- The mainstay symptomatic treatment for cancer pain is opioid-based pharmacotherapy, and all clinicians who provide care to patients with cancer should aim to optimize the positive outcomes from these drugs and minimize the risks associated with both side effects and outcomes related to chemical dependency (misuse, addiction, and diversion)
- Effective opioid treatment depends on appropriate selection of a drug and route, individualization of the dose, consideration of so-called rescue dosing for breakthrough pain, and treatment of common opioid side effects
- The addition of a NSAID to opioid treatment can be helpful, especially in some painful conditions, but the gastrointestinal, cardiovascular, and renal risks of these drugs should be weighed against their benefits on a case-by-case basis
- Adjuvant analgesic drugs, such as glucocorticoids, antidepressants, and anticonvulsants, have many uses when opioid treatment is not sufficient; clinicians should familiarize themselves with the common indications and agents
- Many nonpharmacologic treatments can be used to improve pain control, coping, adaptation, and self-efficacy; mind–body strategies have established benefit and can be used in a restricted but potentially useful manner by nonspecialists
- Interventions, including neural blockade and implanted therapies, play a small but important part in the management of refractory pain

From Portenoy RK. Treatment of cancer pain. *Lancet* 2011;377:2236–2247.

determined, based on the history and examination, and imaging studies. If it is not clear, appropriate investigations should be made to determine the etiology. However, for HNC patients, treatment of moderate or severe pain generally should be initiated while such investigation is undertaken, rather than waiting for a definitive explanation of the pain. Furthermore, the mechanism of the pain (e.g., somatic, neuropathic, or mixed) will be an important consideration in the comprehensive management of the pain. However, as discussed below, opioids are typically indicated for moderate to severe pain, regardless of the mechanism (39,40).

It is important to remember that determinations of the etiology and mechanism of a cancer pain syndrome is rarely definitive—most often it is a reasonable inference based on the information at hand and, therefore, always subject to revision. Furthermore, the response to specific treatments (or lack of response) may provide additional information about the etiology and mechanism—the so-called therapeutic trial. Finally, in any patient with active cancer or undergoing treatment, the pain syndrome may evolve and change over time, so that the clinician should always be alert to new information that may require a change in the treatment plan.

The patient's description of the characteristics of the pain is an important element of the pain history. A useful mnemonic for this purpose is "PQRST," which stands for Provokes or Palliates, Quality, Radiation, Severity, and Temporal course. Specific questions to ask, may include For P: Does anything make the pain better? What makes it worse? For Q: What does the pain feel like (sharp, dull, stabbing, burning, etc.)? For R: Where is the pain? Does it radiate? For S: How severe is the pain? For T: When did the pain start? Has it changed over time?

There are several severity scales available (3). Most widely used is the "Ten-point scale" (actually 11 points, including 0), where 0 = no pain and 10 = "the worst pain you can imagine." For patients who have difficulty with the numeric scale, a descriptive scale of "none, mild, moderate, and severe" often works well. It is useful to ask the patient to rate the pain at its best, its worst, and the usual level of pain. Although, not standardized, it is common to define mild pain as a worst pain score of 1 to 3, moderate pain as a worst pain score of 4 to 6, and severe pain as a worst pain score of 7 to 10.

There are a variety of validated tools to assist the clinician in assessing pain. One widely used tool is the Brief Pain Inventory, which is available online (41).

This information, combined with other clinical information related to the cancer and its treatment, usually will enable the physician to determine the etiology and mechanism of the pain.

Other important aspects of the pain history include the impact of the pain on the patient's function and relationships, any current or past problems with depression, anxiety or other mental illness, current or past personal of alcohol or drug abuse, or family history of alcohol or drug abuse.

In general, there are four major categories of therapies for managing cancer pain: (a) analgesics, including nonopioids and opioids, (b) adjuvant analgesics, including agents targeted to NP, (c) nonpharmacologic therapies, and (d) interventional therapies. The focus of this discussion is the first two categories. Nonpharmacologic therapies are only briefly discussed; interventional therapies are beyond the scope of this chapter and are not discussed.

The WHO Pain Ladder provides guidelines for managing cancer pain, based on the severity and mechanism of the pain (40).

Mild pain—Step 1: Simple analgesics (nonopioid, e.g., acetaminophen, nonsteroidal anti-inflammatory drugs [NSAIDs]); consider adding an adjuvant (e.g., tricyclic antidepressants [TCAs], anticonvulsants) for NP.

Moderate pain—Step 2: Weak opioid (e.g., tramadol, codeine, or hydrocodone); consider adding an adjuvant for NP.

Severe pain—Step 3: Strong opioid (e.g., morphine, oxycodone); consider adding an adjuvant for NP.

For patients with HNC who have moderate to severe pain, most will require treatment with opioids.

A Pharmacologic Approach to Cancer Pain Management

The management of pain in patients with cancer is based on the principle that every patient deserves to have his or her pain assessed and managed in accordance with the best available medical evidence. Specific treatments for specific syndromes, such as mucositis, are discussed elsewhere in this text and are not discussed here. It is well established that opioids are the mainstay of pharmacologic treatment of cancer pain. It is also well established that opioids are associated with certain risks, most notably from side effects, abuse, misuse, and diversion. Misuse behaviors in the medical setting are most-commonly referred to as aberrant drug-related behaviors or, more simply, aberrant behaviors (39). Aberrant behaviors do not necessarily indicate addiction or diversion, but rather raise concern for some form of medication abuse or misuse and therefore warrant careful assessment and monitoring.

Thus every patient who is treated with opioids should be assessed for risk of abuse and addiction and his or her treatment and monitoring should be guided by this assessment. Evidence of aberrant behaviors occurring after treatment has been initiated should lead to reassessment and may require an adjustment of the treatment plan (39,42).

Cancer pain that is severe will typically require opioid therapy. Many patients with moderate pain will require opioid therapy. Opioids are relatively safe if titrated carefully, based on their pharmacologic properties. See Table 22.2 (39) for a summary of basic pharmacologic information about selected opioids.

There are a few general principles that should guide outpatient opioid management of chronic, moderate to severe pain (39,40):

1. Opioid therapy should usually be initiated with the use of short-acting medications, taken on an as-needed (prn) basis, to determine the effective and safe dose. The frequency of dosing should generally be roughly equivalent to the duration of action of the drug.
   a. For opioid-naive patients, the usual starting dose is the equivalent of 5 to 10 mg of oral morphine given every 3 to 4 hours as needed. For opioid-tolerant patients, the dose should be adjusted accordingly.
2. Initial titration should be with a single opioid.
3. The dose may be escalated by 25% to 50% every 24 to 48 hours in the absence of side effects, but slower escalation is acceptable if pain is not severe.
4. Once an effective and tolerated dose is determined, the total 24-hour dose of opioid required to control the pain is calculated.
5. The equivalent of approximately 50% to 75% of the total 24-hour requirement should be provided as scheduled opioids, usually in sustained-release form.
   a. If the opioid used for the scheduled dosing is different than the opioid used in the titration, the dose should be reduced an additional 25% to allow for cross-tolerance.
6. The patient should continue to use a prn dose of a short-acting opioid for breakthrough pain. This dose should be roughly 15% (range 10% to 20%) of the total 24-hour dose and the frequency should be roughly equivalent to the duration of action of the drug.
7. Both the sustained-release and the short-acting opioid should be adjusted as needed for pain control
   a. Sustained release medications should be increased only after reaching steady state (Table 22.2).
8. Methadone should only be used by those who understand its pharmacokinetics and by or under the guidance of those who are familiar with it.
9. All patients taking scheduled opioids should be treated preventatively for constipation and monitored for other side effects.

Special Considerations in HNC

A major distinction in HNC versus the general cancer population is that dysphagia and the frequent dependence on a percutaneous gastrostomy (PEG) tube will limit the options for opioid therapy. Most sustained-release opioids must be taken whole or they become short acting which can result in overdose and even death. Oral sustained-release tablets, such as morphine, oxycodone, hydromorphone, and oxymorphone, should never be crushed or broken for this reason. Therefore, they cannot be used in patients who cannot safely swallow whole pills. They should never be given to be taken per PEG tube or other feeding tube. The exceptions are Kadian and Avinza, sustained-release morphine capsules that can be opened and the contents put into a feeding tube, although this may occasionally clog the feeding tube.

For patients dependent on a feeding tube for their oral medications, there are several options. Liquid medications or crushed short-acting tablets can be administered through the feeding tube. These can be used for both prn and for scheduled dosing. For scheduled dosing, they should usually be given every 4 hours. A fentanyl patch may be used as a sustained-release medication for patients with dysphagia, but dosing conversions can be challenging (39,43). It is recommended that those unfamiliar with fentanyl patches seek guidance from a PC specialist or a pharmacist familiar with opioid therapy.

Methadone is intrinsically long acting and available as a tablet and a liquid and can be given by feeding tube. Methadone's duration of action is quite variable, as is its potency relative to other opioids (44). Converting from other opioids to methadone is challenging. Again, for those unfamiliar with the medication, guidance should be sought from a PC specialist or a pharmacist familiar with opioid therapy (39,40). In addition, methadone may prolong the QTc interval and therefore should be used with caution in patients with cardiac disease or who have other risk factors for QTc prolongation. All patients treated with methadone should have a baseline and follow-up electrocardiograms according to recent published guidelines (45).

Physicians who treat patients with HNC should learn the basic principles of opioid therapy. They should understand the pharmacology of the commonly used medications, as well as the risks and how to mitigate them. They should develop relationships with PC or pain specialists and learn when and how to refer to them.

Neuropathic Pain in HNC

The IASP defines neuropathic pain as "pain caused by a lesion or disease of the somatosensory nervous system" (30). NP in HNC may result from tumor compression or infiltration of the peripheral nerves of the head and neck, trauma or injury to those same nerves as a consequence of surgery or radiation, or the neurotoxic effects of chemotherapy, which may cause local nerve damage or may produce painful neuropathies distant from the primary tumor (e.g., painful polyneuropathy). Secondary illnesses, such as herpes zoster virus, which result from immunosuppressive effects of the cancer or treatments, may also cause NP, either locally or remotely.

The IASP further notes that "NP is a clinical description (and not a diagnosis) which requires a demonstrable lesion or a disease that satisfies established neurologic diagnostic criteria." Despite this caveat, most clinicians and the literature commonly refer to "NP" as a diagnosis. The typical clinical features of NP include the following: it develops in association with a known or presumed injury to the relevant somatosensory nervous system, it may be

TABLE 22.2 SELECTED OPIOID ANALGESIC DRUGS

Drug (and Formulation)	Equianalgesic Doses	Half-life	Duration of Analgesia	Comments
Codeine	200 mg PO	2–4 h	4–6 h	Sometimes used for moderate pain
Hydrocodone	30 mg PO	3–4 h	4–8 h	Used for moderate pain in a combination product containing acetaminophen, ibuprofen, or aspirin.
Morphine	10 mg IM/IV/SQ; 30 mg PO	2–3 h 2–3 h	3–4 h 3–6 h	Standard for comparison for opioids; several routes available
Controlled-release morphine (MS Contin)	30 mg PO	NA	8–12 h	
Extended-release morphine (Kadian, Avinza)	30 mg PO	NA	12–24 h	
Hydromorphone	1.5 mg IM/IV/SQ; 7.5 mg PO	2–3 h; 2–3 h	3–4 h; 3–6 h	Potency and high solubility can be beneficial for patients needing high opioid doses and for subcutaneous administration
Extended-release hydromorphone	7.5 mg PO	NA	24 h	
Oxycodone	20–30 mg PO	2–3 h	3–6 h	Available as a single entity or combined with acetaminophen, ibuprofen, or aspirin
Controlled-release oxycodone	20–30 mg PO	NA	8–12 h	
Oxymorphone	1 mg IM/IV/SQ; 10 mg PO		3–6 h; 4–6 h	
Extended-release oxymorphone (Opana ER)	10 mg PO	NA	12 h	
Methadone	3 mg IM/IV/SQ, 6 mg PO	12–150 h	6–12 h	Dose conversion must be individualized for each patient based on drug, dose, and patient tolerance; these numbers apply to patients taking <100 mg OME per 24 h (44). Can be far more potent than indicated here, presumably because potency of available racemate attributable in part to the D-isomer, an NMDA antagonist that can reverse tolerance and augment analgesia; with highly variable half-life, patients need increased vigilance for weeks, until steady state has definitely occurred; can prolong the QTc interval, so ECG should be monitored according to consensus guidelines (45).
Fentanyl	50–100 µg IV/SQ	7–12 h	1–2 h	
Fentanyl transdermal patch		NA	48–72 h per patch	Not usually recommended for opioid-naive patients in currently available doses; not recommended for acute pain. Because the fentanyl patch is a continuous delivery system, dose to dose conversions are not applicable; the recommended conversion is based on 24-h use of oral or parenteral opioids: 60 mg OME/24 h = 25 mcg/h fentanyl patch (43).
Transmucosal fentanyl citrate formulations		7–12 h	1–2 h	New formulations indicated for the treatment of breakthrough pain; available in various forms, including buccal lozenge, buccal tablet, buccal patch, sublingual, and intranasal formulations; not recommended for opioid-naive patients; starting dose for breakthrough pain should always be one of the lowest doses available, even if the patient is receiving a high dose of a scheduled opioid

PO, by mouth; IM, intramuscular; IV, intravenous; SQ, subcutaneous; NA, not applicable; PR, by rectum; OME, oral morphine equivalents; NMDA, *N*-methyl-D-aspartate. ECG, electrocardiogram.
From Portenoy RK. Treatment of cancer pain. *Lancet* 2011;377:2236–2247 (slightly revised).

associated with altered sensory function, it is commonly described as burning, pricking, sharp, stabbing, hot, cold, squeezing, or electric-shock-like, and may be characterized by typical neuropathic features, such as allodynia (non-painful stimuli producing pain) or hyperalgesia (mildly painful stimulation producing severe pain).

Several sources provide excellent information about treating NP in patients with cancer (46,47). A recent authoritative review of the pharmacologic management of NP, published in the journal *Pain* (47), is available online and provides detailed evidence-based recommendations for the treatment of NP associated with cancer. A brief summary of their recommendations includes

Step 1

A. Establish the diagnosis of NP; if uncertain, refer to a pain specialist or neurologist
B. Establish and treat the cause, if possible
C. Identify relevant comorbidities or associated symptoms that might influence treatment decisions or require dosage adjustments (e.g., cardiac, renal, or hepatic disease, depression, ataxia)
D. Explain the diagnosis and treatment to the patient and establish realistic expectations.

Step 2

A. Initiate treatment with one or more of the following first-line medications:
   a. nortriptyline or desipramine—secondary amine TCAs or duloxetine or venlafaxine—selective serotonin and norepinephrine reuptake inhibitors (SNRIs)
   b. gabapentin or pregabalin (sometimes referred to as gabapentinoids)
   c. topical lidocaine, if pain is localized
   d. opioid analgesics or tramadol for prompt relief of moderate to severe pain

Recommendations are included regarding starting and maximum dosages, as well as titration schedules, for each of the above medications.

Step 3 involves reassessment and additional trials of first-line medications, either alone or in combination. Step 4 recommends that if trials of first-line medications fail, the clinician should consider trials of second- and third-line medications or referral to a pain specialist. Discussion of second- and third-line medications is beyond the scope of this chapter.

The choice of specific agents will depend primarily on comorbidities and associated symptoms and side effects (46,47). For example, TCAs may cause dry mouth and urinary retention, and should be used with caution in patients with significant cardiac disease, seizures, suicide risk, or in combination with tramadol (due to increased risk of serotonin syndrome), but may improve depression and insomnia. SNRIs may cause nausea and should be used with caution in patients with hepatic or renal dysfunction, cardiac disease, or in combination with tramadol, but may improve depression. Gabapentin and pregabalin may cause sedation, dizziness, and peripheral edema, and should be used with caution in renal insufficiency, but have no clinically relevant drug interactions and may improve sleep. Topical lidocaine may cause local skin irritation, but has no systemic side effects at standard doses. Opioids and tramadol may cause constipation, nausea and vomiting, drowsiness, and dizziness (most side effects, except for constipation are usually transient) and should be used with caution in patients with a history of, or at risk for, substance abuse, but have a rapid onset of analgesia. Tramadol also may increase seizure risk and should be used with caution in combination with TCAs or SNRIs.

A pragmatic approach to the treatment of NP in HNC based on the above recommendations would be

1. For patients who are depressed or have insomnia, who have no contraindications, to initiate treatment with a TCA or SNRI.
2. For patients who are not depressed, do not have insomnia, or have a contraindication to a TCA or SNRI, to initiate treatment with a gabapentinoid.
3. For patients with relatively localized pain, consider combining topical lidocaine with any of the above.
4. For patients with moderate to severe pain or those who have mixed pain, opioid therapy should usually be combined with any of the above; however, use caution for patients with a history of, or at high risk for, substance abuse (see above discussion).

END-OF-LIFE CARE FOR PATIENTS WITH HNC

Physicians should attempt to provide the most appropriate—that is, most beneficial, least harmful—treatment for each patient, based on the medical situation. Extensive research over the last several years supports the assertion that involvement of PC and hospice is essential to providing optimal care for patients whose death is anticipated. Indeed, late referral for PC or hospice can result in increased and unnecessary suffering for both the patient and family (48).

Many of the issues that patients dying of HNC must face are similar to those faced by any patient dying of cancer or any other progressive disease. As with most cancers, patients who die of HNC typically deteriorate fairly gradually and their death rarely comes completely without warning. Nevertheless, because physicians are often reluctant to discuss patients' prognoses with them and their families, many patients and families are unaware that death is approaching until death is very near (49). For HNC patients, as for other cancer patients, as death approaches, appropriate care must include attention to psychosocial and spiritual aspects of care—attending to the needs not

only of the patient, but also the family. Many issues that arise, including psychosocial, spiritual, and existential, may be beyond the capacity of the physician to address adequately. This is another reason to involve PC and hospice, which typically include mental health professionals, pastoral care, and other specialties; together such teams can provide the holistic interdisciplinary care necessary to address the complex challenges faced by dying patients and their families. Patients and families often struggle with the realization that the patient has reached a point that anticancer treatment will no longer benefit the patient. The perception that "there is nothing else we can do" is both disheartening and false. Indeed, the unofficial motto of PC is: "Actually, there is more we can do." For patients who are dying, PC and hospice are not about doing less, they are about doing those things that are most appropriate for dying patients, that is, most likely to benefit and least likely to harm them. Because presenting the option of PC and hospice as a positive good for dying patients is often a challenge for those who have little experience with such care, it is often beneficial to encourage patients and families to at least meet with PC or hospice representatives who can present the most accurate explanation of the benefits (50).

An important consideration for patients who are recognized to be dying is to address resuscitation status. It is important to understand that, for patients dying of advanced cancer, cardiorespiratory arrest is the mechanism of death, not the cause of death (51). This is an important difference between dying patients and other seriously ill patients, including many HNC patients who are not imminently dying, for whom a cardiorespiratory arrest may be the cause of death—that is, but for the cardiorespiratory arrest, the patient is not imminently dying. Whereas it makes sense to attempt resuscitation when the arrest is the potential cause of death, it does not make sense to attempt to treat an arrest that is merely the mechanism of death. With this in mind, when discussing resuscitation status with imminently dying patients and their families, rather than simply asking their preferences, it is appropriate to *recommend* that resuscitation *not* be attempted at the time of death. An example of a "script" to be used for such patients is "Unfortunately, because we cannot treat your underlying disease, it will soon cause your death. When that happens, your heart will stop beating and your breathing will stop. Therefore, I would recommend that, when that happens, we focus on assuring that you die peacefully and comfortably, rather than using shocks and machines to try to restart your heart or breathing. Does that make sense to you?" This approach is discussed in greater detail in a recent article (51).

Another medical issue that is often of critical importance for patients with HNC is correctly understanding—and explaining to the patient and family—when the provision of artificial hydration and nutrition is appropriate and beneficial and when it is inappropriate and harmful. Although this is an issue that is relevant to all dying patients, it is of particular importance for patients with HNC as many will have feeding tubes in place and would have been receiving AHN for some time prior to entering the dying process. As with any treatment, it is important to understand it in the medical context, considering the benefits and risks specific to that context. It is also important to consider the symbolic meaning of providing AHN—that is, feeding symbolizes sustenance and nurturing—and to distinguish that from the actual medical consequences.

The key point is that (for patients without feeding tubes) it is the natural course of the final stages of the dying process that essentially all patients lose their appetite and, eventually, their ability to swallow. Dying patients stop eating because they are dying; they do not die because they stop eating. As their gastrointestinal system begins to shut down, along with all other organ systems, they can no longer process and absorb hydration and nutrition. Furthermore, as their kidneys and heart fail, any excess fluid in their system tends to accumulate in their lungs causing pulmonary edema and respiratory distress. Indeed, this is one of the most common causes of distress in dying patients. In patients without feeding tubes, the discontinuation of feeding tends to occur naturally and is often recognized as a natural part of the dying process. However, in patients who have feeding tubes, the decision to discontinue AHN must be made deliberately and should be done according to the medical condition of the patient, for example, when gastrointestinal symptoms or evidence of fluid overload begin to develop—preferably earlier rather than later. Often, AHN can be gradually weaned as the patient declines, to minimize the risk of adverse symptoms. It is optimal to discuss this eventuality with patients and families ahead of time, so they can ask questions and prepare themselves psychologically for the terminal phase of the dying process. Once again, this discussion is often best accomplished with the help of PC and hospice personnel who are familiar with the natural dying process—another reason why early referral to PC or hospice is beneficial to patients and families.

Defining a Good Death

One important question, which can be addressed both philosophically and empirically, is what constitutes a "good death?" Steinhauser et al., used focus groups and in-depth interviews of a wide range "of persons involved with EOL care—physicians, nurses, social workers, chaplains, hospice volunteers, patients, and recently bereaved family members," in an attempt to provide an empirically based description of a good death (52). They found six components that were widely endorsed as essential components of a good death

- Pain and symptom management
- Clear decision making
- Preparation for death

- Completion
- Contributing to others
- Affirmation of the whole person

Not surprisingly, the importance of managing pain and other symptoms remained a paramount consideration for all groups. This reiterates the importance of providing excellent and appropriate medical care to dying patients. However, the main message of this study is that providing excellent medical care, although necessary, is not sufficient to ensure a good death.

Among the needs expressed by providers and families was the need for improved communication and clearer decision making, to improve the chances that a patient's preferences were known before a medical crisis occurs. The "lack of opportunity to plan ahead, arrange personal affairs, decrease family burden, or say good-bye" was identified as contributing to a bad death. The authors comment that "for dying patients and their families, preparation does not preclude hope; it merely frames it." The concept of "completion" is related and helps explain the importance of providing honest, compassionate prognostic information. Completion involves spending "meaningful time with family and close friends and attention to religious or spiritual beliefs." They note that terminally ill patients often frame the experience of dying within the larger trajectory of their life, thereby identifying and responding to opportunities for healing of relationships and personal growth. This may be part of the reason that terminally ill patients often rate their own QOL higher than observers.

The authors were somewhat surprised that a common theme was the desire of patients to contribute to others, but noted that "social psychologists describe this need for 'generativity' as one of the great emotional tasks of human development, particularly during later life." The focus groups also emphasized the importance of recognizing and appreciating dying patients as "whole persons," rather than primarily as persons with an illness or disease.

Specific Considerations in EOL Care for Patients with HNC

Due to the anatomical features of their disease, many patients with HNC have problems that are more or less specific to HNC. Among the problems that are common in patients with HNC are problems related to communication, swallowing, breathing, and the risk of catastrophic bleeding. A few studies have investigated this specific population and provide some insight into these and other problems and some guidance on how to best manage them.

A retrospective study from Taiwan addressed symptom patterns in HNC patients cared for on an inpatient palliative care unit (PCU) by a multidisciplinary team consisting of physicians, nurses, psychologists, social workers, pastors, and volunteers (53). Patients were typically referred late in their disease and had an average survival of about 22 days after admission to the PCU. Overall, the most common symptom was weight loss, followed by pain, cough, dysphagia, feeding difficulties, and communication difficulties. The only symptom that significantly correlated with the presence of a tracheostomy was communication difficulties. They found that pain was poorly controlled on admission and that opioid doses were typically increased after admission. Among their most interesting findings was a correlation between higher levels of education and higher doses of opioids. Most intriguing was their observation that the change (increase) of opioid dosage after PCU admission correlated with longer survival ($p < 0.001$). This supports the contention, often expressed by those experienced in EOL care, that optimizing pain control tends to prolong survival, presumably by diminishing distress and allowing better function, including better nutrition and increased activity. At the very least, this observation contradicts the widely believed myth that increasing opioid dosages at the EOL hasten death.

Another retrospective study, from Germany, presents a rather grim picture of the final days of patients with advanced HNC (54), describing the challenges encountered by an inpatient hospice team caring for 16 patients dying of HNC. The authors of this study note that Germany is about "25 years behind" Britain and the United States in the development of PC and hospice care, which may explain some of the findings of this study. Average survival after admission in this study was 19.5 days. In this group, pain was reported to be well managed on admission and aggressive opioid protocols generally maintained good pain control. One of the most common and challenging problems encountered was communication, largely related to tracheostomy and also impaired mental status. Several patients (it is not clear exactly how many) had large, exophytic tumors with skin breakdown, infection, and even maggot infestation in three patients. This was the most distressing problem encountered by staff and was also distressing to patients and families. Five patients had ongoing alcohol addiction and were permitted to continue their usual alcohol intake, either orally or per feeding tube. Fourteen of the 16 patients were visited fairly regularly by family members. None of the patients died alone; nine died in the presence of at least one family member and seven deaths were attended by a nurse. This emphasizes the relative predictability of death in advanced HNC. None of the patients suffered a catastrophic bleed.

In an American study, Shuman et al performed a survey of 58 surviving relatives of patients who died of HNC, using a variation of a validated survey instrument, the Family Assessment of Treatment at the End of Life (FATE), which consists of an overall score and nine domain scores (higher scores indicate greater satisfaction) (55). In their study, they evaluated the overall score and two domain scores, Management of Symptoms (MOS) and Care at the Time of Death (CTD). Approximately, one-third of the patients died in the hospital, the remainder died at home or in inpatient hospice (the exact numbers in each

of the latter two categories is unclear). Sixty-nine percent of patients had a PC consult, 90% had advance directives. There was no difference in overall FATE scores between patients with metastatic (45% of patients) versus locoregional disease (55%). Patients who died in the hospital had significantly lower overall FATE scores, as well as lower MOS and CTD scores, than those who died in hospice or at home. PC consult correlated with higher CTD scores, but not overall FATE or MOS scores. A history of palliative chemotherapy or radiotherapy correlated with higher MOS and CTD scores, but not overall FATE score.

One final consideration specific to HNC is the risk of terminal hemorrhage. Terminal hemorrhage—in HNC usually resulting from tumor eroding into the carotid artery—is typically an extremely distressing event for the patient and family and health care providers. Mercifully, such hemorrhages invariably result in rapid loss of consciousness, followed rapidly by death. The primary approach to management includes recognizing the risk and assuring that a sufficient quantity of dark towels are readily available to absorb the large quantity of blood and provide coverage of the wound. An additional option is to attempt to rapidly provide sedative or opioid medication to alleviate the patient's suffering. However, a recent study evaluating the use of anticipatory crisis anxiolytic or opioid medications for terminal hemorrhage through retrospective structured interviews of PC and head and neck oncology nurses, concluded that "anticipatory prescribing of crisis medication rarely benefits the patient and may unintentionally detract from nursing care" (56). The authors recommend focusing instead on providing nonpharmacologic management for patients with terminal hemorrhage.

These studies illustrate some of the challenges specific to the management of patients dying of HNC, as well as the value of an interdisciplinary team in providing EOL care. Experience with the dying process in general, and with the dying process of patients with HNC, is an important benefit provided by PC and hospice.

CONCLUSION

Patients with advanced, recurrent, or progressive HNC present a variety of challenges to the clinicians caring for them. Many of the challenges are common to all cancer patients with advanced disease, but many of the challenges are specific to patients with HNC.

Managing pain is a common challenge and all clinicians who care for patients with HNC should attempt to develop competence in the basics of cancer pain management. Patients with complex pain and other physical symptoms are likely to benefit from referral to a PC team. PC not only provides expert management of pain and other physical symptoms, it provides interdisciplinary care to address the multitude of complex problems experienced by patients with HNC, including psychosocial, spiritual, and existential problems.

Antineoplastic strategies (chemotherapy, radiation, surgery) can be considered in patients with incurable HNC carefully weighing factors such as expected symptomatic benefit, potential morbidity, patient performance status, and realistic patient and family expectations. Most common palliative antineoplastic strategies involve chemotherapy/systemic therapy. Symptomatic benefit occurs more often in patients who experience reduction in tumor burden, although symptomatic improvement can also occur in the absence of overt disease response.

It is important to recognize when patients are nearing the end of their lives, in order to ensure that they receive optimal care at that critical time. The most important considerations when patients are dying are to ensure comfort for the patient and support for the patient and family. This is best provided through PC or hospice referral. Learning to present PC and hospice as a positive option for patients with advanced disease is essential. Patients only die once. Although it is always tragic when patients die, it is doubly tragic when patients and families do not receive the support and care available to mitigate their suffering.

HIGHLIGHTS

- The goal of Palliative Care is to prevent and relieve suffering and to support the best possible quality of life for patients and their families, regardless of the stage of their disease or the need for other therapies.
- The Report of the National Consensus Project Clinical Practice Guidelines for Quality Palliative Care describes the eight essential domains that must be addressed by all clinical PC programs:
  - Structure and Processes of Care
  - Physical Aspects of Care
  - Psychological and Psychiatric Aspects of Care
  - Social Aspects of Careo
  - Spiritual, Religious, and Existential Aspects of Care
  - Cultural Aspects of Care
  - Care of the Imminently Dying Patient
  - Ethical and Legal Aspects of Care
- Antineoplastic strategies (chemotherapy, radiation, surgery) can be considered in patients with incurable head and neck cancer (HNC) carefully weighing factors such as expected symptomatic benefit, potential morbidity, patient performance status, and realistic patient and family expectations. Most common palliative antineoplastic strategies involve chemotherapy/systemic therapy. Symptomatic benefit occurs more often in patients who experience reduction in tumor burden, although symptomatic improvement can also occur in the absence of overt disease response.
- Pain in HNC can occur as a result of the disease itself or therapy. The evidence suggests that

  - The majority of patients with HNC will have pain, which may be difficult to treat. Pain may be somatic, neuropathic, or mixed.
  - Up to a quarter of patients who remain disease free at 2 years may have persistent pain, which may be moderate to severe in up to 15%.
  - Persistent shoulder and arm pain is associated with neck dissection.
  - Of the HNC patients who seek treatment for pain, the most common sites of pain are the head, face, mouth, and neck.
- The management of pain in patients with cancer is based on the principle that every patient deserves to have his or her pain assessed and managed in accordance with the best available medical evidence.
- Opioids are the mainstay of pharmacologic treatment of cancer pain; however, they are associated with certain risks, most notably side effects, abuse, misuse, and diversion. Misuse behaviors in the medical setting are most-commonly referred to as aberrant behaviors.
- Every patient who is treated with opioids should be assessed for risk of aberrant behaviors and his or her treatment and monitoring should be guided by this assessment. Evidence of aberrant behaviors occurring during treatment should lead to reassessment and may require an adjustment of the treatment plan.
- Physicians who treat patients with HNC should learn the basic principles of opioid therapy. Because neuropathic pain is common in HNC, they should also learn the basic principles of treating NP. They should understand the pharmacology of commonly used medications, as well as the risks and how to mitigate them. They should develop relationships with PC or pain specialists and learn when and how to refer to them.
- Extensive research over the last several years supports the assertion that involvement of PC and hospice is essential to providing optimal care for patients whose death is anticipated.
- For HNC patients, as for other cancer patients, as death approaches, appropriate care must include attention to psychosocial and spiritual aspects of care—attending to the needs not only of the patient, but also the family.
- Whereas it makes sense to attempt resuscitation when an arrest is the potential cause of death, it does not make sense to attempt to treat the mechanism of death. With this in mind, when discussing resuscitation status with imminently dying patients and their families, it is appropriate to *recommend* that resuscitation *not* be attempted at the time of death.
- One study suggested that the essential components of a good death are
  - Pain and symptom management
  - Clear decision making
  - Preparation for death
  - Completion
  - Contributing to others
  - Affirmation of the whole person
- Patients only die once. Although it is always tragic when patients die, it is doubly tragic when patients and families do not receive the support and care available to mitigate their suffering.

EMBRYOLOGY

Embryologic development of the nasal cavity and sinuses leads to the intricate features of sinonasal anatomy and can be divided into two ongoing processes. First, the embryo's head develops into a structure with two distinct nasal cavities; second, the lateral nasal walls then invaginate to create complex folds, known as turbinates, and spaces, known as sinuses. During the fourth to eighth gestational weeks, the embryo develops separate nasal cavities as the frontonasal and maxillary processes join. The frontonasal process grows over the developing forebrain, contributing to the formation of the nasal olfactory placodes. Medial and lateral nasal prominences develop on either side of the placode eventually becoming the nares. The nasal placode invaginates to form the nasal pit and eventually the nasal sac. Fusion of the medial nasal prominence with the maxillary process forms the upper maxilla and the philtrum of the upper lip (Fig. 23.1). The septum arises from the posterior midline growth of the frontonasal process and midline extensions of mesoderm from the maxillary processes. The primary and secondary palatal shelves join in an axial plane to separate the nasal cavity and nasopharynx from the oral cavity and oropharynx. The descending septum merges with the fused palate to create two distinct nasal cavities (Fig. 23.1). Fusion failure of the medial nasal prominence with the maxillary process or fusion failure of the palatal shelves results in a cleft lip or palate deformity. Because clefting can extend into the nose, rhinoplasty to correct an associated nasal deformity is often technically difficult.

During the sixth gestational week, mesenchyme forms a simple lateral nasal wall. During the seventh week, three axial furrows form, giving rise to the three turbinates (Fig. 23.1). During the 10th week, development of the maxillary sinus begins with the invagination of the middle meatus. At the same time, the uncinate process and the bulla ethmoidalis form a narrow groove known as the hiatus semilunaris. During the 14th week, the anterior ethmoidal cells appear as several invaginations from the upper middle meatus and the posterior ethmoidal cells from the floor of the superior meatus. Finally, by the 36th week the lateral nasal wall is well developed and the turbinates are at adult proportions. All paranasal sinuses are present to varying degrees in the newborn, but sinuses have specific periods of significant growth. The ethmoid sinuses are the first to fully develop, followed in order by maxillary, sphenoid, and frontal sinuses.

ANATOMY

Refer to Figure 23.2 for illustrations of sinus anatomy discussed in the text.

Ethmoidal Sinuses and Lateral Nasal Wall

The ethmoid sinuses are the central structures of the nose with complex anatomy; they are best visualized as a box-like structure with open anterior and inferior faces. The lateral portions form the medial walls of the orbits, the sphenoid establishes the posterior face, the superior surface is formed by the skull base of the anterior cranial fossa, and many of the key structures of the lateral nasal wall, derived from basal lamellas, extend posteroinferiorly from the skull base.

The lateral wall of the ethmoid sinus, or lamina papyracea, forms the paper-thin medial wall of the orbit. The midline vertical plate of the ethmoid bone is composed of a superior portion in the anterior cranial fossa called the crista galli and an inferior portion in the nasal cavity called the perpendicular plate of the ethmoid bone that contributes to the nasal septum. The anterior cranial fossa is separated from the ethmoid air cells superiorly by the horizontal plate of the ethmoid bone, which is composed of the thin medial cribriform plate and the thicker, more

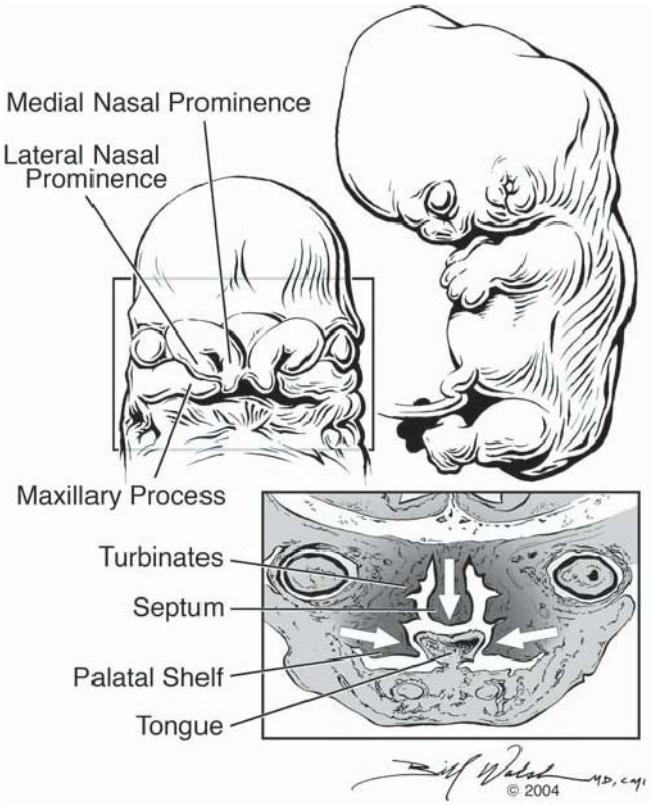

Figure 23.1 A 7-week gestational age embryo. Cross-section in **bottom right** shows the formation of turbinates and the separation of the nasal cavities by fusion of the nasal septum with the palatal shelves. Illustration by William E. Walsh, MD, CMI ©2004, used with permission.

lateral ethmoid roof. The ethmoid roof articulates with the cribriform plate at the lateral lamella of the cribriform plate, which is the thinnest bone in the entire skull base. The length of the lateral lamella depends on the position of the cribriform plate with respect to the ethmoid roof. In a Keros type 1 skull base, the plate is located 1 to 3 mm below the roof of the ethmoid, making the lateral lamella short or nonexistent (Fig. 23.2B). In Keros type 2, the distance is 4 to 7 mm. In Keros type 3, it is 8 to 16 mm, thus giving rise to a long vertical lateral lamella (Fig. 23.2C). Patients with a low cribriform plate, *Keros III in particular*, are believed to be at greatest risk for cerebrospinal fluid leak during endoscopic sinus surgery.

The ethmoid sinuses are separated by a series of recesses demarcated by five bony partitions or lamellae. These lamellae are named from the most anterior to posterior: first (uncinate process), second (bulla ethmoidalis), third (basal lamella), fourth (superior turbinate), and fifth (supreme turbinate). These partitions aerate during development forming the ethmoid air cells. If the aeration projects anterior to the attachment of the middle turbinate, the air cells are termed agger nasi cells. Continuing posteriorly, the uncinate process is an L-shaped bone that runs in an anterosuperior to posteroinferior direction. The posterosuperior margin of the uncinate runs parallel to the anterior border of the bulla ethmoidalis and the posterior end attaches to the palatine bone and the inferior turbinate. The superior portion of the uncinate most commonly attaches to the lamina papyracea but can also attach to the posteromedial wall of the agger nasi cell, the skull base, or the middle turbinate. The bulla ethmoidalis, or second lamella, gives rise to the most constant and usually largest anterior ethmoid air cell. It attaches laterally to the lamina papyracea and to a varying degree posteriorly to the ground lamella. Superiorly, the bulla may reach the roof of the ethmoid and form the posterior wall of the frontal recess. Minimal or absent pneumatization of the ethmoid bulla occurs in 8% of individuals (1). The basal lamella marks the dividing line between the anterior and posterior ethmoid sinuses. The inferior portion of the basal lamella connects the middle turbinate to the lateral nasal wall obliquely transitioning from a coronal plane anteriorly to an axial plane posteriorly. Preservation of the lower portion of the basal lamella during endoscopic sinus surgery provides stability to the middle turbinate. Posterior ethmoidal cells are generally larger and can pneumatize laterally and superiorly to the sphenoid sinus. This developmental variant is known as an Onodi cell, a risk factor for dehiscence and potential injury to the optic nerve during surgery.

The lamellae of the ethmoid sinuses are separated by a series of four recesses: the frontal recess, the infundibulum, the sinus lateralis, and the sphenoethmoidal recess. The frontal recess drains the frontal sinus; the anatomy is highly variable depending on the pneumatization patterns of the bulla ethmoidalis and agger nasi air cells (2). The ethmoidal infundibulum is a three-dimensional space lateral to the uncinate process. Between the free concave posterior margin of the uncinate process and the convex anterior face of the bulla ethmoidalis is a two-dimensional cleft called the hiatus semilunaris that serves as the door that leads anteriorly into the infundibulum. The ostium of the maxillary sinus lies deep within the ethmoidal infundibulum lateral to the uncinate process. The ethmoid sinuses anterior to the basal lamella, the maxillary sinus, and the frontal sinus all drain directly into or near the infundibulum. The ostiomeatal complex (OMC) refers to the area bounded by the middle turbinate medially, the lamina papyracea laterally, the basal lamella posteriorly, and the ethmoid roof superiorly (1). A sinus lateralis or retrobullar recess exists if the posterior wall of the bulla ethmoidalis aerates to become distinct from the basal lamella. The sphenoethmoidal recess is located at the posterior end of the superior meatus draining the posterior ethmoid and sphenoid sinuses separately, outside of the OMC.

The anterior ethmoid artery originates from the ophthalmic artery in the orbit and passes through the anterior ethmoidal foramen to enter the anterior ethmoidal cells. The artery typically crosses the ethmoids very near the skull base at the junction of the ethmoid roof and marks the posterior border of the frontal recess; the artery travels within a bony canal that may be partially or completely dehiscent in 40% of cases (1). The area where the anterior ethmoid

artery enters the anterior cranial fossa through the lateral lamella is the weakest portion of the skull base, being only one-tenth as strong as the roof of the ethmoid (1).

Maxillary Sinus

The maxillary sinus is the pneumatized space within the maxillary bone and is the largest of the paranasal sinuses. The anterior wall derives from the facial surface of the maxilla, the posterior wall borders the pterygopalatine fossa, the medial wall constitutes the lateral wall of the nasal cavity, the floor of the sinus is the alveolar process, and the superior wall serves as the orbital floor. The infraorbital nerve crosses the orbital floor to exit the anterior portion of the maxilla via the infraorbital foramen. The canal for the infraorbital nerve is dehiscent into the maxillary sinus in 14% of cases and may be at risk during endoscopic sinus surgery. The first and second molar tooth roots are dehiscent into the maxillary sinus occurring in 2% of cases. These patients are at risk for development of an oroantral fistula following dental extraction at these sites.

The natural ostium of the maxillary sinus opens into the superior aspect of the medial wall to drain into the ethmoidal infundibulum. Accessory maxillary sinus ostia are found in 15% to 40% of subjects, most commonly superior and posterior to the uncinate process above the insertion of the inferior turbinate. Occasionally a Haller cell, or ethmoidal cell that pneumatizes laterally between the maxillary sinus and the floor of the orbit, may be present. The presence of Haller cells can potentially narrow the maxillary infundibulum and impair sinus drainage (3).

Frontal Sinus

The size of the frontal sinus varies depending on the degree of pneumatization, may be completely absent (5%), and is usually divided by an intersinus septum. The anterior table of the frontal sinus is twice as thick as the posterior table, which separates the sinus from the anterior cranial fossa. The floor of the sinus also functions as the supraorbital roof, and the drainage pathway is located in the posteromedial portion of the sinus floor. Drainage of the frontal sinus is complex with its outflow tract resembling an hourglass-shaped structure in the sagittal plane (1,2). The superior portion widens into the frontal sinus and the inferior portion expands into the frontal recess. The variability of the frontal sinus outflow tract drainage pattern depends on the pneumatization of the surrounding ethmoid air cells and the position of the uncinate process. A markedly pneumatized agger nasi cell or ethmoidal bulla can obstruct frontal sinus drainage by narrowing the frontal recess. Drainage of the frontal sinus also depends on the attachment of the superior portion of the uncinate process (4). In the most common variation, the anterosuperior portion of the uncinate process inserts onto the lamina papyracea so that the uncinate process separates the ethmoidal infundibulum from the frontal recess. In this setting, the frontal recess opens into the middle meatus medial to the ethmoidal infundibulum, between the uncinate process and the middle turbinate (Fig. 23.2C). When the uncinate process inserts onto the ethmoid roof (Fig. 23.2B) or inserts onto the middle turbinate (Fig. 23.2A), the frontal recess opens directly into the ethmoidal infundibulum, and is thought to be subject to obstruction in the presence of ethmoid inflammation. During endoscopic sinus surgery, the opening of the frontal sinus is often more medial than anticipated. The frontal sinus opens into the middle meatus medial to the uncinate process in 88% of patients and lateral to the uncinate in the remaining 12% of patients.

Sphenoid Sinus

The sphenoid sinus has many important neurovascular relationships. The internal carotid artery is lateral to the sphenoid sinus as it courses through the cavernous sinus producing a prominence in the lateral sphenoid sinus wall in 65% of individuals (3). Approximately 25% of bony capsules separating the internal carotid artery from the sphenoid sinus are partially dehiscent. An optic nerve prominence is present in 40% of individuals with dehiscence in 6% (3). The visibility of all structures related to the walls of the sphenoid sinus depends on the degree of pneumatization of the sinus. The degree of pneumatization is classified into three types: sellar type (86%), presellar (11%), and conchal type (3%) (3). Presellar and conchal types are more common in children due to the normal development of the sphenoid sinus reaching completion at 20 years of age. In a sellar type sphenoid sinus, the superior wall pneumatizes inferiorly to the sella turcica and the pituitary gland. The posterior wall of the sphenoid sinus is the clival wall and is the thickest wall of the sphenoid sinus.

The sphenoid sinus ostium opens into the sphenoethmoidal recess. An anatomic study of the sphenoid sinus ostium identified the posteroinferior end of the superior turbinate as the best landmark for identifying the natural ostium of the sphenoid sinus (5). In most cases, the posteroinferior end of the superior turbinate was located in the same horizontal plane as the floor of the sphenoid sinus. The ostium was located medial to the superior turbinate in 83% of cases and lateral to it in 17%. The sphenoid septum usually deviates posteriorly from the midline dividing the sinus into two asymmetric parts and can insert onto the bony prominences overlying the optic nerve or carotid artery.

Inferior Turbinate

The inferior turbinates are bilateral outgrowths from the lateral wall of the nasal cavity composed of a central bony skeleton covered by a mucosal layer. Each inferior turbinate articulates with the perpendicular plate of the palatine bone and the nasal surface of the maxilla. The inferior turbinate swells and shrinks to regulate nasal temperature and humidification via a rich vascular arcade.

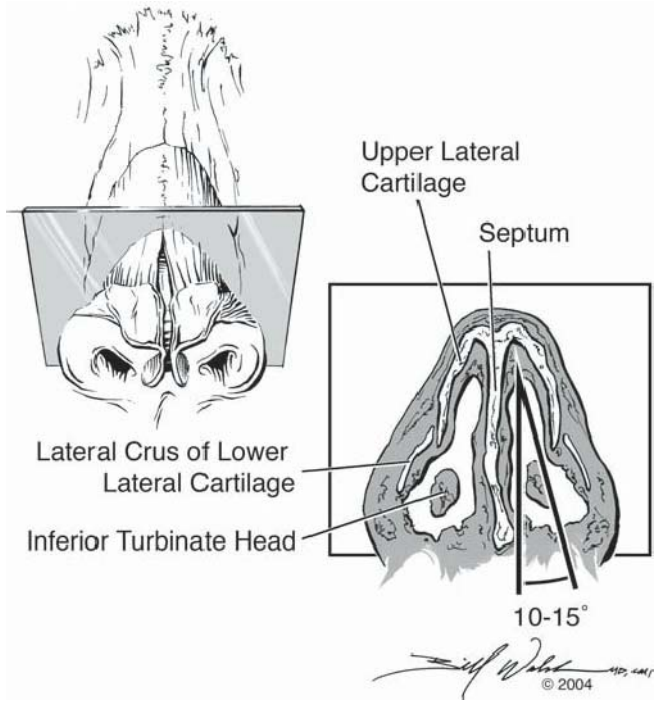

Figure 23.4 Nasal valve. Illustration by William E. Walsh, MD, CMI ©2004, used with permission.

Nasal Septum

The septum separates the two nasal cavities, provides structural support for the nose, and influences airflow in the nasal cavity. The septum is made of a sagittal plate of cartilage and bone covered by respiratory mucosa. The membranous septum connects the columella to the quadrangular cartilage. The quadrangular cartilage comprises the majority of the anterior septum. The perpendicular plate of the ethmoid bone forms the bony upper one-third of the nasal septum and the vomer makes up its bony posteroinferior portion. Finally, the nasal, frontal, maxilla, and palatine bones each contribute nasal crests to the periphery of the septum (Fig. 23.3).

Nasal Valve

The nasal valve is the mobile, airflow-regulating part of the nose that serves as the bridge between the bony skeleton and the nasal tip. This valve is the narrowest part of the nasal airway and poses the greatest resistance to nasal airflow. The nasal valve includes the area between the caudal end of the upper lateral cartilages and the superior septum. These segments usually form an angle of 10 to 15 degrees (Fig. 23.4). A decreased angle can induce airflow turbulence and nasal obstruction. The nasal valve region is bordered superolaterally by the caudal edge of the upper lateral cartilage. The lateral border includes the bony piriform aperture and the fibrofatty tissue of the ala. The nasal valve ends inferiorly at the nasal floor. Finally, the head of the inferior turbinate forms the posterior limit of the nasal valve (Fig. 23.4).

ANATOMIC CAUSES OF NASAL OBSTRUCTION

The trigeminal nerve endings in the nasal cavity provide the sensation of nasal airflow, and blockage of these receptors results in the sensation of nasal obstruction (6). A variety of intranasal deformities cause nasal obstruction and evaluation of each of the anatomic causes allows the surgeon to select the best procedure to correct the obstruction. This evaluation begins with a careful history and physical examination. Patients may report nasal congestion, stuffiness, or blockage; they may also report poor quality sleep or difficulty breathing during sleep. In addition to a fixed, anatomic obstruction, the physician must carefully seek other causes of nasal obstruction such as allergic rhinitis (AR), acute or chronic sinusitis, or medication-induced rhinitis. The physical examination includes external and internal nasal examination by anterior rhinoscopy and nasal endoscopy followed by a repeat examination after nasal decongestion. Obstruction that resolves with decongestion is caused by mucosal abnormality.

Septal Deviation

Patients with a symptomatic septal deviation complain of chronic obstruction that is frequently unilateral, possibly with a distant history of nasal trauma. They are often

keenly aware of the nasal cycle. Anterior rhinoscopy and nasal endoscopy documents the presence and degree of septal deviation. In addition, assessment of the columella from below helps evaluate caudal septal deflections, which can be underestimated on standard rhinoscopy. Palpation of the external nose and septum tests the support of the dorsum and the tip.

The treatment for nasal obstruction from septal deviation is septoplasty. Patients with septal deformity who undergo septoplasty generally report significant improvement in nasal obstruction at 3 and 6 months and use fewer medications (7). Unfortunately, no single test reliably predicts successful outcome preoperatively. Rhinomanometry has been used as an adjunctive research tool to document obstruction and degree of improvement postsurgery, but these tests are not widely used in the clinical setting. The location of the septal deformity strongly correlates with the surgical outcome and the postoperative airway resistance. Even minor septal deviations in the anterior part of the nose in the region of the nasal valve often result in significant nasal obstruction because the nasal valve is the critical resistive area of the nasal cavity; posterior deviations must be of great size to result in noticeable nasal obstruction.

Nasal Valve Collapse

The nasal valve is the narrowest part of the nasal airway accounting for most of the resistance to airflow; abnormalities in this region readily cause nasal obstruction. Two types of nasal valve dysfunction can occur: one involves dysfunction in the region of the nasal valve and the other involves collapse of the structures itself. Obstruction in the region of the nasal valve is most commonly from turbinate hypertrophy or septal deviation. The second type of nasal valve dysfunction results from collapse of the structure itself. Most cases are iatrogenic and nasal valve collapse must be considered in any patient who reports long-term obstruction postrhinoplasty. However, a small percentage of cases are congenital. Physical findings typically include an hourglass or pinched appearance of the middle segment of the nose, medial collapse of the alar cartilage on deep inspiration, or deep alar grooves. In the performance of rhinoplasty, nasal valve dysfunction results from aggressive narrowing of the nasal tip, over resection of the lateral crus, displacement of weak alar cartilages, excessive narrowing of the dorsum, over resection of upper lateral cartilages, or displacement of short nasal bones. A variety of surgical techniques have been developed to correct nasal valve dysfunction including spreader grafts, alar batten grafts, flaring sutures, overlay grafts, and lateral suture suspensions. Spreader grafts can be sutured along the length of the upper lateral cartilage to increase the cross-sectional area of the internal nasal valve and to augment the nasal structure preventing collapse. Alar batten grafts support flaccid lower lateral cartilages. Flaring sutures dilate the caudal margin of the upper lateral cartilages. Although these techniques correct nasal valve obstruction, each of these procedures may have aesthetic consequences.

The Cottle maneuver is the traditional method to diagnose nasal valve collapse. This maneuver widens the alae by placing lateral traction on the cheek. Some believe that the Cottle maneuver is a nonspecific test that improves breathing even when nasal obstruction is secondary to septal deviation or turbinate hypertrophy. To address this objection, a modified Cottle maneuver has been proposed to more specifically diagnose nasal valve collapse (8). In this modified maneuver, an ear curette separately supports the lower and upper lateral cartilages to see if nasal patency is increased.

Turbinate Hypertrophy

The inferior turbinate also affects airflow at the nasal valve depending on the degree of anterior turbinate engorgement. During inspiration, the anterior tip of the inferior turbinate in the region of the nasal valve generates up to two-thirds of upper airway resistance (9). Inferior turbinate enlargement leads to symptoms of nasal obstruction by increasing resistance. AR, nonallergic rhinitis, and rhinitis medicamentosa cause turbinate inflammation. If the inflammation persists, mucous glands grow in size and collagen accumulates beneath the nasal mucosa basement membrane resulting in irreversible hypertrophy.

Medical treatment for inferior turbinate hypertrophy includes *antihistamine nasal sprays*, decongestants, intranasal corticosteroids, mast cell stabilizers, and immunotherapy. A variety of surgical techniques also treat the nasal obstruction arising from turbinate hypertrophy and each methodology attempts to minimize complications such as bleeding, discomfort, and atrophic rhinitis while restoring normal turbinate size and function.

Concha Bullosa

A pneumatized middle turbinate, known as a concha bullosa, is one of the most common anatomic variations of the middle meatus with a reported incidence greater than 25%. The interior of a concha bullosa contains a lining of respiratory epithelium and drains through an ostium into the frontal recess, sinus lateralis, or hiatus semilunaris (1). The middle turbinate may grow to such an extent that it fills the space between the lateral nasal wall and the septum resulting in nasal obstruction and predisposing to sinus infection by blocking the OMC. Concha bullosa is suspected when an enlarged middle turbinate is observed during nasal endoscopy. A computed tomography (CT) scan demonstrating pneumatization of that turbinate confirms the diagnosis. Endoscopic excision of the lateral wall of the pneumatized turbinate can address this type of obstruction.

Choanal Atresia

Choanal atresia is a rare cause of nasal obstruction resulting from failure of the posterior choanae to develop properly. This condition occurs in 1 per 5,000 births with a female-to-male preponderance of 2:1. The extent of the atresia determines the severity of obstruction. Because newborns are obligate nose breathers, bilateral choanal atresia results in severe nasal obstruction and immediate airway distress relieved by crying. The diagnosis is suspected by the inability to pass a catheter or nasogastric tube on either side. Unilateral choanal atresia does not immediately threaten the child's life and usually presents in late childhood or young adulthood with unilateral nasal obstruction, rhinorrhea, or obstructive sleep apnea. Endoscopic assessment and CT scanning of choanal atresia can establish the diagnosis, characterize the lateral wall component of the atresia, evaluate the bony or membranous composition, and monitor the extent of surgical correction (10). The diagnosis of choanal atresia suggests the presence of other medical conditions and should prompt an evaluation for otitis media with effusion, upper and lower airway diseases, cardiac anomalies, and gastrointestinal (GI) tract disorders. Bilateral choanal atresia can coexist with cardiac disorders, CHARGE syndrome (colobomas, heart defects, choanal atresia, retarded growth, genitourinary hypoplasia, and ear anomalies), obstructive sleep apnea, hematologic problems, and failure to thrive (10).

In a large series of children treated for choanal atresia, the majority of children underwent transnasal repair with or without stenting. Other procedures performed less frequently include posterior septal window or dilation for unilateral choanal atresia, and transpalatal repair with stenting for bilateral choanal atresia. The repair of bilateral choanal atresia with dilation and removal of stents, on average, requires more procedures than unilateral choanal atresia to achieve a patent nasal airway without respiratory distress (10). The use of fibroblast-inhibiting topical mitomycin at the time of surgery may lead to improved patency.

Nasal Polyposis

Nasal polyposis (NP) is believed to be a multifactorial disorder characterized by the presence of edematous masses in the nasal cavity and sinuses triggering drainage, smell loss, and obstruction. The specific causes of NP remain unclear, but allergy, asthma, chronic rhinosinusitis (CRS), aspirin intolerance, and cystic fibrosis have been implicated in various studies. The majority of nasal polyps (80% to 90%) exhibit tissue eosinophilia and factors that could potentially trigger mucosal eosinophilia have been suggested as etiologic agents. Sinonasal inflammation from any etiology is believed to cause polyps to increase in size and number, with resultant nasal obstruction and sinus ostial blockage often triggering infectious sinusitis.

Intranasal and systemic steroids are the most common treatments for the management of nasal polyps. If evidence of purulence is seen on endoscopy, antibiotics are added to the treatment regimen. Endoscopic surgery is reserved for severe nasal obstruction resistant to maximal medical therapy. Nasal polyps tend to be more severe and refractory to medical and surgical treatment, especially in the subset of aspirin-sensitive asthmatics (11).

PHYSIOLOGY

The three major functions of the nose are olfaction, respiration, and protection. These functions are aided by the convoluted anatomy of the nasal cavity, which creates a large surface area. This mucosal lined, moist, ciliated surface of the nasal cavity increases contact with inspired air, thus maximizing olfaction, and resulting in efficient heating, humidifying, and filtering of inspired air before reaching the lower airways.

Respiration

The extensive vascular and secretory systems of the nasal cavity and paranasal sinuses serve to warm and humidify ambient air in preparation for access to the lower airways. The nose warms inspired air to 37°C facilitating alveolar gas exchange. This warming capacity is not overburdened even at 7 L per minute of inspired airflow (12). Independent of the environmental humidity, the sinonasal system can raise the humidity of inspired air to approximately 85%, thus decreasing the drying effect of inspired air and significantly benefiting gas exchange in the lower airways (12). This moisture comes from the water content of the mucus that is directly transudated from nasal blood vessels and supplied by nasal glands.

Turbulent nasal airflow is central to the physiology of the nose. Turbulent airflow occurs even at low air velocities in most parts of the nasal cavity and increases with higher air velocities (9). Turbulence increases contact between inspired air and the nasal mucosa enhancing not only the respiratory functions but also olfaction and protection. The main airflow passes over the head of the middle turbinate through the middle meatus with only minor changes in flow pattern as velocity increases. The percentage of air passing through the middle meatus increases with increased nasal congestion (9).

Nasal airway resistance can be divided into three parts: the nasal vestibule, the nasal valve, and the turbinated nasal cavity. The nasal vestibule contributes approximately one-third of nasal resistance. The compliant walls of the nasal vestibule are susceptible to collapse from the negative pressure created during inspiration; however, the facial muscles attached to the nasal vestibule contract during inspiration to splint the vestibule and prevent collapse. As previously mentioned, the nasal valve is the narrowest part of the nasal passage with the highest resistance. Venous sinusoids

control nasal airflow; thus, venous sinusoids of the anterior portion of the inferior turbinate and the nasal septum in the region of the nasal valve most significantly contribute to total nasal airflow resistance. The turbinated cavity of the nasal passage with its larger cross-sectional area contributes only minimally to nasal airway resistance (6).

The nasal submucosa is rich in vasculature including arterioles, capillaries, and venules. The mucosa of the inferior turbinate uniquely contains many small veins, called venous sinusoids. To cause expansion of this erectile tissue that brings congestion, these high capacitance sinusoids relax to fill with blood; in contrast, decongestion of the nose results from contraction of the sinusoids emptying them of blood. Sympathetic vasoconstrictor stimulation exerts the major control over venous sinusoid filling by decreasing the volume of blood held in the mucosa causing decongestion. Parasympathetic vasodilator fibers exert only minor control of nasal blood volume but cause more potent control of nasal secretions by stimulating a watery discharge. In general, sympathetic innervation controls nasal airflow and parasympathetic innervation controls nasal secretions (6).

In addition to autonomic regulation of nasal vasculature, nasal airflow is also influenced by the nasal cycle, head and body position, exercise, and nitric oxide (NO). The nasal cycle refers to spontaneous congestion and decongestion alternating between the two nasal passages. This cycle occurs in approximately 80% of the population and repeats every 0.5 to 3.0 hours. The nasal cycle results in airway resistance and nasal width changes that affect airflow turbulence. Although the resistance and airflow alternates between the two nasal cavities, the nasal cycle does not significantly change the combined nasal resistance and total airflow. Postural change can alter nasal airflow through changes in relative venous pressure. Exercise results in epinephrine release causing nasal decongestion. Sex hormones influence nasal airflow; thus, pregnancy, puberty, and menstruation can lead to increased nasal obstruction (6). Lastly, the neurotransmitter NO contributes to nasal blood flow regulation and mucus production. Nasal NO concentrations depend on nasal airflow but not on changes in the nasal cavities induced by the nasal cycle or posture. Increased nasal airflow from nasal decongestion removes NO from the nasal cavity and transports it to the lung where NO serves as a vasodilator gas. Conversely, decreased nasal airflow during congestion results in an elevated nasal NO concentration. While in the nasal passages, NO influences nasal cilia; higher concentrations stimulate nasal ciliary beat frequency, whereas low NO concentrations depress this frequency. Higher nasal ciliary beat frequency may help protect the nasal airway during congested states like acute sinusitis.

Nasal resistance can be measured using *rhinomanometry*. Rhinomanometry measures the airflow at a fixed pressure differential during the respiratory cycle. Airflow is measured directly with a mask. Transnasal pressure is simultaneously measured with pressure detectors at different locations depending on the technique. Anterior rhinomanometry measures transnasal pressure one nostril at a time at the nasal orifice; posterior rhinomanometry measures nasal resistance of both nostrils simultaneously with a pressure detector placed in the mouth. The information is recorded and displayed on a pressure-flow curve. Because nasal resistance is the ratio of pressure to airflow, the pressure-flow curve will show that at a given transnasal pressure, the more obstructed nose will achieve less airflow and thus display a higher resistance.

Nasal cross-sectional area can be measured using *acoustic rhinometry*. Acoustic rhinometry is a noninvasive way to measure cross-sectional area of the nasal cavity by analyzing reflected sound waves within the nasal cavity. Acoustic pulses enter the nasal passage through a nose piece, impact nasal structures, and are reflected back to a microphone. The reflected pulse is presented as an area-distance plot. The area of maximal narrowing corresponding to the nasal valve usually lies within the first 2 cm of the nasal vestibule. The next downward deflection in the acoustic rhinometry curve usually corresponds to the narrowing caused by the head of the inferior turbinate at the piriform aperture. According to Poiseuille's law, nasal airflow is directly proportional to the radius to the fourth power. Thus, any narrowing in the nasal airway significantly decreases flow. Acoustic rhinometry characterizes the geometry of the nasal cavities, quantifies nasal obstructions, and monitors results of medical or surgical treatment. Results have been validated with imaging studies. Acoustic rhinometry area measurements are most accurate for the anterior part of the nose, especially the nasal valve region (13).

The techniques of rhinomanometry and acoustic rhinometry give complementary information: rhinomanometry determines resistance or how hard it is to breathe, whereas acoustic rhinometry allows localization of abnormalities. Both techniques have been used extensively in the scientific study of the nose, although they have not entered into the everyday practice of rhinology. Some authors believe that these techniques are impractical in everyday office practice and the findings often do not correlate with patients' perception of nasal obstruction (8).

Olfaction

Olfaction is discussed in detail in *Chapter 24*. Briefly, the olfactory centers are housed within the sinonasal tract. Anatomically, the olfactory neuroepithelium is scattered through the superior portions of the nasal cavity, located between the septum and medial surface of the superior turbinate bilaterally. The olfactory neuroepithelium may extend anteriorly onto the middle turbinate, and inferiorly below the cribriform plate. This area is known as the olfactory cleft. Odorants reaching the olfactory cleft may be nasal or retronasal. Nasal stimulation results in the

conventional sense of olfaction, while retronasal stimulation plays a role in the sensation of flavor during the ingestion of food.

Histology of the olfactory neuroepithelium consists of various cell types. Primarily, the mucosa consists of pseudostratified columnar epithelium. Basal cells in the deeper layers give rise to the differentiated neural and nonneural cellular elements. Microvillar sustentacular cells reside at the epithelial surface and provide metabolic support to the neurons. Bowman glands extend ducts from the basement membrane to the epithelial surface. Olfactory neuron cell bodies reside superficial to the basal cells. Dendrites terminate in knobs at the epithelial surface, containing olfactory receptors. Axons extend through the lamina propria and converge with other axons to form nerve bundles, or fila olfactoria. These fila then proceed through the cribriform plate and form first-order synapses at the olfactory bulb, part of cranial nerve I. These neurons are unique in their capacity to communicate directly between the external environment and the central nervous system, as well as their ability to regenerate.

Each olfactory receptor represents a different receptor type. Work by Buck and Axel identified genes encoding nearly 1,000 different transmembrane G-protein receptors. Groups of receptor types are organized into zones, although the distribution within these zones is seemingly random. Axons will converge with similar receptor types on approach to the glomeruli within the olfactory bulb. Each odorant activates a different set of receptors and glomeruli, resulting in unique patterns of activation.

Protection

Normal sinonasal mucosa is made of an epithelial layer, lamina propria, submucosa, and periosteum. The nasal epithelial cells are ciliated, pseudo-stratified, columnar cells with a variable number of goblet cells. A thin layer of acellular basement membrane separates the epithelial layer from the thick lamina propria. Beneath the epithelium reside lymphocytes, plasma cells, and macrophages as well as vascular arcades and glands. Nasal airflow interfaces with the mucosa exposing it to a constant load of particulate matter. Turbulent airflow forces all inspired air to contact mucosal surfaces before passing to the lower airways. Coarse nasal hairs, vibrissae, located at the nasal orifice filter out large particles entering the nose. Smaller particles impact the mucosa as a result of turbulent flow and stick to the nasal mucus. Particles smaller than 0.5 μm pass through the nasal filter to the lower airways. Mucociliary clearance serves to transport trapped particles including pathogens out of the sinuses and nose. The mucous blanket is divided into the inner sol layer and outer gel layer. Goblet cell–produced glycoproteins give the gel layer of nasal mucus its viscosity and elasticity. The gel layer lies on top of the nasal cilia, whereas the sol layer surrounds the cilia. The sol layer of mucus is considerably less viscous so that ciliary movement can propel the overlying layer of mucus and any trapped particles.

In all the sinuses, mucus moves toward the natural ostia. Maxillary sinus mucociliary clearance begins at the floor and flows against gravity toward the maxillary infundibulum. The anterior ethmoids drain into the middle meatus and the posterior ethmoid cells drain into the superior meatus. Mucus in the frontal sinus drains toward the ostium only from the lateral side. Mucus medial to the ostium must course superiorly to join the lateral flow toward the ostium. Like the maxillary sinus, the sphenoid sinus flows against gravity toward its ostium that drains into the sphenoethmoidal recess. Once mucus has drained from the sinuses into the nasal cavity, mucus flow is toward the nasopharynx. Mucus from the anterior sinuses passes over the inferior turbinate and then anterior to the eustachian tube orifice, whereas posterior sinus secretions pass posterior to the eustachian tube.

The mucous blanket is cleared toward the nasopharynx every 10 to 15 minutes by ciliary movement and replaced by fresh mucus secreted by the nasal cavity and sinus mucosa (1). Ciliary activity can be impaired by a humidity drop, temperature decrease, or cohesion created by opposing mucosal surfaces. Mucociliary transit time is measured by the *saccharin test*. A saccharin pellet is placed in the anterior part of the nasal cavity, dissolves, and is transported by the mucociliary system into the nasopharynx, and then the oropharynx where the sweet taste is detected. Normal transport times are less than 20 minutes, with most subjects detecting the taste within 10 minutes. Other methods are also available (12).

Recurrent sinus infections resulting from increased mucociliary transit time are most commonly associated with primary or secondary ciliary dysfunction. Primary ciliary dyskinesia (PCD) is an autosomal recessive disorder resulting from defective ciliary structure and function. Fifty percent of patients with PCD have Kartagener syndrome with bronchiectasis, sinusitis, and situs inversus. Panrespiratory disease is highly associated with PCD; sinonasal disease is the most common manifestation, but otitis media and pulmonary disorders are also highly prevalent. PCD is diagnosed using the clinical features together with measurement of nasal NO and evaluation of ciliary ultrastructure. On electron microscopic studies, cilia from patients with PCD show a high percentage of anomalous cilia with absent or reduced dynein arms, absent radial spokes, translocation of microtubular doublets, or altered central pairs. Ciliary ultrastructural and functional studies may be normal in some cases of PCD when strong clinical features are present. Conversely, PCD can be excluded if clinical features are weak and NO levels are normal. Cystic fibrosis must be excluded in all cases. PCD and secondary ciliary dyskinesia (SCD) are functionally similar but ultrastructurally different. SCD usually occurs during or after a respiratory infection and is often reversible. SCD is characterized by a low percentage of anomalous cilia and by

a pattern of secondary ultrastructural changes: compound cilia, peripheral microtubule addition or deletion, disorganized axonemes, ciliary disorientation, discontinuity of axoneme membrane, and swollen cilia with excess cytoplasm (14).

The nasal mucosa interfaces with the external environment, interacting with a constant load of bacteria, viruses, and fungi. In the normal individual, the mucosal immune system responds to this stimulation by functioning as a first line of defense against invading pathogens without excessive tissue reaction or collateral damage (15). Two distinct, yet integrated responses to microbial pathogens and foreign proteins have been described: innate and acquired immunity. The innate immune system refers to any inborn resistance that is already present the first time a pathogen is encountered. The innate immune response is modified only in quantitative rather than qualitative terms following repetitive exposure. Respiratory epithelium forms the first line of nasal defense by creating a physical barrier bound with tight junctions. The nasal mucosa secretes enzymes and peptide antibiotics with direct antimicrobial effects in mucus. Neutrophils and macrophages, which phagocytose microbes, form the next line of defense. The epithelium and the phagocytes distinguish self from nonself by soluble and membrane-bound pattern recognition receptors that recognize pathogen associated molecular patterns (PAMPs) found in parasites, viruses, bacteria, yeast, and mycobacteria. These receptors serve two basic functions. First, they may recognize and bind pathogens in the airway mucus and epithelium facilitating phagocytosis (e.g., macrophage mannose receptor). Second, binding to receptors such as the Toll family triggers the secretion of mediators directly affecting pathogen clearance (e.g., interferon) and the attraction of additional phagocytes (16). If the stimulus is sufficiently strong, a secondary acquired immune response will occur.

The acquired immune response across the sinonasal tract is mediated by dendritic cells (DCs), which are phagocytic antigen-presenting cells present in substantial numbers in the nasal mucosa. In the GI tract, DCs perform a sentinel function by sampling the surrounding environment to distinguish invasive pathogens from commensal organisms, apparently through molecular pattern recognition, thereby regulating mucosal immunity (17). Although the normal GI flora usually induces tolerance, an excessive immunologic response to these nonpathogens is believed to result in inflammatory bowel disease. The upper respiratory tract, although not sterile, does not demonstrate the same degree of commensal colonization seen in the GI tract. Nonpathogenic bacteria, pathogenic bacteria, and fungi have been cultured from the upper respiratory tracts of asymptomatic individuals, but it remains unclear whether these organisms always incite an immune response or whether tolerance can develop (18). Moreover, precise characterization of the "normal flora" of the upper respiratory tract is lacking and it is unclear whether the presence of nonpathogenic bacteria serves protective functions by inhibiting the growth of other microbial agents.

The acquired immune response in the nose centers around the processing and presentation of antigen by DCs to T-helper (Th) cells. The interaction between DCs, T cells, and B cells may take place locally in lymphoid mucosal aggregates as well as in draining lymph nodes (15). T and B cells travel to draining lymph nodes and return to effector sites in the mucosa via the bloodstream. The nature of the effector response is heavily dependent on the strength of the PAMP stimulus and resulting cytokine milieu. In the presence of a typical strong PAMP stimulus, a skewed Th1 response is triggered emphasizing a cell-mediated response with potent antiviral and antibacterial effects (19). The Th1 response, with attendant cytokines, facilitates macrophage–phagocytic activity and cell-mediated cytotoxicity. On the other hand, weak PAMP stimuli (or as yet unidentified type 2 specific PAMPs) result in a skewed Th2 response emphasizing IgE and secretory IgA (S-IgA) antibody production with the attraction of mast cells, basophils, and eosinophils (15,19,20). Th2 cells produce cytokines that affect antigen-specific B cells, triggering Ig class switching resulting in IgE- and IgA-secreting plasma cells in the nasal mucosa. S-IgA is the major immunoglobulin in nasal secretions interacting with microorganisms by directly neutralizing some viruses, initiating antibody-dependent cell-mediated cytotoxicity, and interfering with some bacterial growth factors (20). Th2 responses also address multicellular parasites, which are too large to be engulfed by macrophages but demonstrate vulnerability to eosinophils. Th17 responses are thought to play a role in the defense against extracellular bacteria (20). Th1, Th2, and Th17 responses reciprocally inhibit one another; typical chronic *in vivo* immune responses are polarized to one or the other type. Meanwhile, Treg cells have been found to suppress Th1, Th2, and Th17 responses, limiting excessive immune responses (21). Some degree of balance is necessary in contrast to unopposed type 1 or type 2 responses, which manifest as disease in animal models (19). Although the outline of nasal immunity delineated previously is derived from current evidence, one should remember that new data from the rapidly developing area of mucosal immunology will modify these concepts. In particular, the number of Th subsets is likely to expand.

In addition to protective immunity, Th2 effects mediate allergic disorders. AR is an inflammatory disease of the nasal mucosa that initiates the release of mediators from antigen-sensitized immune cells. Allergens are typically protein antigens with weak PAMPs, interacting with DCs to trigger a Th2 response. Activated Th2 cells induce the conversion of B cells to plasma cells that produce IgE specific to that allergen. These specific IgE antibodies attach to the surface of mast cells in the nasal mucosa. At the next exposure, allergen crosslinks the specific IgE antibodies attached to mast cells and induces those mast cells to release preformed inflammatory mediators that result in

the early-phase symptoms of AR. The late-phase symptoms are associated with the subsequent infiltration of inflammatory cells, including eosinophils that further amplify the inflammatory allergic response. Many clinically significant allergens are proteases that attack the epithelial barrier including tight junctions, thus increasing access to DCs and sensitized mast cells (22). The *in vivo* and *in vitro* tests used to diagnose AR demonstrate the presence of systemic IgE, which correlates with an immunologic mechanism for Th2 responses mediated across the nasal mucosa and elsewhere (23). Recent reports have suggested that local Th2-driven or IgE-mediated disease may exist in the nose without evidence of systemic IgE sensitization (24,25). The mechanism as well as the clinical significance for this process remains uncertain.

The sinonasal tract constantly interfaces with the external environment; foreign antigens are encountered and typically cleared. However, in more than 10% of the population, this stimulation triggers a chronic inflammatory infiltrate in the nasal mucosa resulting in the clinical symptoms of CRS (26). The immunodominant antigenic stimuli, presumably microbial, remain unclear although both *Alternaria* fungi and *Staphylococcus aureus* have been proposed (27,28). Much of the current research on CRS, however, has focused interest away from potential pathogens onto identification of defects in the host immune response (29,30,31,32). Increased understanding of the normal immune response of the nasal and sinus mucosa will likely be necessary to make progress in the management of this widely prevalent disorder.

HIGHLIGHTS

- Sinonasal embryology can be divided into two ongoing processes: first, the embryo's head develops into a structure with two distinct nasal cavities; second, the lateral nasal walls then invaginate to create complex folds, known as turbinates, and spaces, known as sinuses.
- The ethmoidal, maxillary, sphenoid, and frontal sinuses make up the paranasal sinuses.
- The complex and variable anatomy of the lateral nasal wall influences approaches to endoscopic sinus surgery.
- A variety of intranasal deformities cause nasal obstruction and evaluation of each of the anatomic causes allows the surgeon to select the best procedure to correct the obstruction.
- The three major functions of the nose are olfaction, respiration, and protection; these functions are aided by the convoluted anatomy of the nasal cavity, which creates a large surface area.
- Turbulent nasal airflow is central to the physiology of the nose. Turbulence increases contact between inspired air and the nasal mucosa enhancing not only the respiratory functions but also olfaction and protection.
- The nasal valve is the narrowest part of the nasal passage with the highest resistance; thus, venous sinusoids of the anterior portion of the inferior turbinate and the nasal septum in the region of the nasal valve most significantly contribute to total nasal airflow resistance.
- Rhinomanometry measures nasal resistance; acoustic rhinometry measures nasal cross-sectional area.
- Coarse nasal hairs, vibrissae, located at the nasal orifice filter out large particles entering the nose, smaller particles impact the mucosa as a result of turbulent flow and stick to the nasal mucus. Mucociliary clearance serves to transport trapped particles including pathogens out of the sinuses and nose.
- Recurrent sinus infections resulting from increased mucociliary transit time are most commonly associated with primary or secondary ciliary dysfunction.
- The nasal mucosa interfaces with the external environment, interacting with a constant load of bacteria, viruses, and fungi. In the normal individual, the mucosal immune system responds to this stimulation by functioning as a first line of defense against invading pathogens without excessive tissue damage.

Olfaction

24

Eric H. Holbrook *Donald A. Leopold*

Anyone who has experienced complete nasal obstruction from an infection or severe allergic rhinitis has suffered the loss of a sense that is often taken for granted. In other mammals, the sense of smell is absolutely crucial for survival, reproduction, and rearing of young. Although humans can survive without olfaction, the negative impact on quality of life has been well documented with some approaching clinical depression (1–3). As other animals depend on the sense of smell as an alarm system for danger, we also depend on the sense of olfaction to warn us of smoke, natural gas leaks, and spoiled food. On a more frequent occasion, people with smell loss struggle with the blandness of meals and have difficulty with the appropriate use of bodily hygiene products or perfumes. In the food industry, olfaction is crucial to chefs and wine tasters and its loss can be devastating.

The overall prevalence of olfactory dysfunction includes 19% of the population over the age of 20 and 25% of the population over the age of 53 (4,5). If smell loss from aging alone is considered, one out of eight people between the ages of 53 and 91 will acquire an olfactory impairment over a 5-year period (6). Many patients will report a loss in taste when in reality they are experiencing a decrease in flavor due to a lack of sense of smell. Regardless, the effect is the same and especially in the elderly population, the impact on diet and nutrition can be significant (7,8).

This chapter describes the main causes of olfactory disorders and provides a logical guideline to the evaluation and treatment (when available) of patients with smell dysfunction. The following commonly used definitions describe olfactory disorders. The complete absence of a sense of smell is termed anosmia, while hyposmia is a decreased sense of smell. Dysosmias are alterations (decreases or distortions) in smell. A smell perceived in the absence of a true odor in the environment is termed phantosmia, while an altered perception of an odor in the environment different from what is usually experienced for that odor is termed parosmia.

ANATOMY

The nasal cavity is the conduit for odors to reach the specialized neuroepithelium that converts binding of odorant molecules by receptors into electrical signals that extend to the brain. Many studies have looked at airflow properties of the nasal cavity and ability to smell. Although severe nasal obstruction from septal deviation can reduce odorant access to the olfactory nerves, it is rarely the sole cause of olfactory loss. Retronasal presentation of odors during eating has been given increasing importance for adding separate qualities to the overall appreciation of flavor of food (9,10).

Ultimately, odorants need to interact with olfactory receptors that reside in a patch of olfactory epithelium located in the superior/posterior-most aspect of the nasal cavity, the olfactory cleft. This area is variable in size and variable in the extensiveness of small patches of respiratory epithelial replacement. The overall area averages 1 to 2 cm^2 in adults, but covers a much larger region in infants (11). The decrease in olfactory epithelium over time and the presence of respiratory patches within the olfactory epithelium is speculated to be caused by cumulative environmental insult and subsequently a source for olfactory loss with aging. The olfactory epithelium covers a region of the septum below the cribriform plate extending back to the face of the sphenoid (12). A similar sized region apposed to the septal olfactory mucosa is present laterally within the olfactory cleft on the middle and superior turbinates. The narrowness of this space may protect the delicate olfactory neurons from environmental damage, but may increase susceptibility to obstruction from inflammatory processes with resulting smell loss.

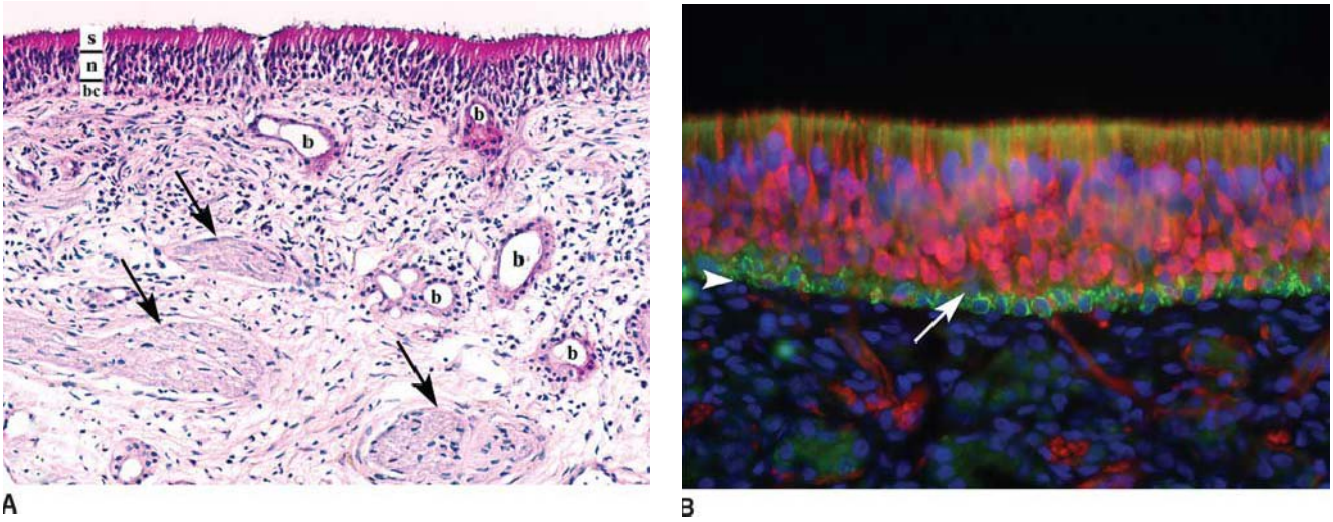

Figure 24.1 Human olfactory mucosa. **A:** Hematoxylin and eosin stain of human olfactory mucosa (200×). The epithelium can be divided into a basal cell layer (*bc*), neuronal layer (*n*), and supporting cell layer (*s*) where the cell bodies of each of these cell types typically reside. The underlying lamina propria contains Bowman glands (*b*) and fila olfactoria (*arrows*) with multiple olfactory receptor axons. **B:** Immunohistochemical staining of human olfactory epithelium (400×). Olfactory neurons with their dendrites and axons are labeled *red* with an antibody directed against PGP9.5. The fine dendrites are seen extending between supporting cells and ending in knobs at the apical surface, while the axons exit through the basal lamina (*white arrowhead*) to converge and join the fila olfactoria. Horizontal basal cells (HBCs) are labeled *green* with antibodies against keratin 5 and reside on top of the basal lamina. Unstained cells between the HBCs and neurons are likely globose basal cells (*arrow*). Supporting cell nuclei are seen as the row of *blue* (DAPI stained) nuclei above the neuronal layer.

The olfactory mucosa is composed of a pseudo-stratified neuroepithelium (Fig. 24.1). Supporting cells populate the apical portion of the epithelium and send foot processes to the basal lamina. The dendritic knobs of the olfactory neurons with their multiple immotile cilia extend above the apical surface of the supporting cells, but the cell bodies of the neurons reside in the midsection of the epithelium with the more mature neurons taking a more apical position. The axons extending from these bipolar cells extend through the basal lamina and converge with other olfactory axons to form bundles (fila olfactoria) that transverse the cribriform plate and innervate the brain within the olfactory bulbs at synaptic collections termed glomeruli. These axons are unique in several aspects: they are true receptor neurons with direct synapses to the brain, they are the only cranial nerve (CN I) with direct exposure to the environment, and they are continually replaced throughout our lifetime. Signal projections from the olfactory bulb travel through the lateral olfactory tracts and synapse on several higher locations including the anterior olfactory nucleus, amygdala, piriform cortex, and entorhinal cortex. Major projections to structures associated with the limbic system and hippocampus explain the often-experienced relationship of specific odors with a strong emotional response or triggering of a vivid memory associated with the odor.

The cells responsible for the replacement of these neurons as well as replacing other cells comprising the epithelium are the horizontal and globose basal cells positioned just above the basal lamina. Unique to the olfactory mucosa are Bowman glands within the lamina propria that send ducts through the epithelium to the apical surface providing mucus that is likely important in the presentation of odorants to the olfactory receptors. Although there is variation in the thickness of the epithelium and less ordered positioning of the olfactory neurons within the epithelium compared to that found in rodents, the architecture and cellular components are remarkably similar in humans (12).

PHYSIOLOGY OF OLFACTION

The detection and identification of a specific odor from the multitude of complex odors present in the environment is only partially understood. The initial site of interaction between an odorant molecule and the olfactory neuron, the olfactory receptor, has now been identified (13). These receptors collectively form a family of similar G proteins (G_{olf}) that when activated stimulate adenylate cyclase to synthesize cyclic adenosine monophosphate (cAMP). cAMP acts as a second messenger to open a cyclic nucleotide-gated ion channel allowing for influx of cations and depolarization of the neuron. There are approximately 1,000 different genes within the olfactory receptor gene family in rodents; many however are pseudogenes. The human olfactory gene family with 339 intact receptor genes and 297 pseudogenes has fewer receptor genes than mice; however, this gene family still comprises one of the largest

gene families in the human genome (14). In rodents, it has been shown that each olfactory neuron expresses only one member of the olfactory receptor genes. Neurons expressing like receptors are restricted to a regional zone oriented from a dorsal–medial to ventral–lateral orientation; however, within these regions, the expression pattern appears random among other receptors expressed in the similar area. These neurons expressing like receptors extend axons that remarkably converge together within the lamina propria to eventually converge exclusively to, on average, two glomeruli within each olfactory bulb (15). In humans, this receptor-to-glomeruli ratio is much broader and calculated to be on the order of 1:16 (16). This receptor-specific patterning is the basis of an odorant map whereby an odorant stimulates a subset of olfactory neurons that in turn activate a specific set of glomeruli in the olfactory bulb (17,18). Therefore, an odor is coded by the multiple receptor neurons it stimulates and in turn the resulting unique pattern of glomerular activation is transmitted in an unclear fashion to higher brain centers and perceived as a smell.

ETIOLOGY OF OLFACTORY LOSS

Numerous causes for a decrease in ability to smell have been described, but multiple reports from various smell and taste centers have consistently recognized similar etiologies (19). The three most common are smell loss relating to head trauma, upper respiratory infection (URI), and chronic rhinosinusitis (CRS). Another large category of smell loss is idiopathic smell loss in which no identifiable source of olfactory dysfunction can be determined. There is also a known progressive loss of sense of smell across the population related to aging with a significant drop in ability after the age of 65 and occurs in greater than one-half of people between the ages of 65 to 80 (20). The cause of this age-related loss is unclear but is independent of neurodegenerative disease. Possible theories for this loss include eventual wear-and-tear of the olfactory neurons from the cumulative effect of exposure to environmental toxins and/or progressive depletion of the regenerative capacity of epithelial basal/stem cells and genetically programmed cell death.

Smell loss related to head trauma is usually easily identified by history; however, even mild injuries to the head can result in significant olfactory disability (21). Often, in severe head trauma, the loss of smell is recognized relatively late in the recovery period due to cognitive alterations and the presence of additional separate severe injuries. The loss is thought to be a result of injury to the frontal lobes and olfactory bulbs through direct injury or commonly from a blow to the back of the head and rebound contusion to the frontal regions through a coup-countre coup injury. Another possible mechanism of traumatic smell loss is through the shearing of olfactory neurons where they transverse the cribriform plate as the brain and olfactory bulbs violently shift during trauma. Recovery from traumatic smell loss is variable but sometimes permanent with rare complete recovery and improvement in only 10% to 35% of patients (22–24). Usually, if return of function occurs, it generally begins within a year of the trauma.

Transient smell loss often occurs with URIs due to inflammatory swelling and obstruction of the olfactory clefts. Less commonly, a longer lasting or permanent deficit occurs after recovery from a URI. Although never confirmed, the loss is thought to be a result of a viral infection. Parainfluenza 3 has been implicated as the possible viral agent based on epidemiologic studies and molecular analysis of nasal epithelium from patients with URI-related anosmia (25,26). Even less clear is the site and mechanism of damage. Epithelial abnormalities have been found in many biopsy studies, but damage isolated to the olfactory bulbs is also possible. Women are afflicted more commonly than men in this type of smell loss, and the elderly may be more susceptible. It more often results in hyposmia instead of anosmia and the chance for recovery is relatively higher than other common forms of smell loss (27) with recovery rates between 32% and 67% (22,23).

CRS is often associated with a decreased or absent ability to smell. This can occur either with or without polyps commonly resulting from obstruction of odorant flow to the olfactory cleft. A description of fluctuating ability to smell with periods of complete return of function is rarely attributed to anything other than CRS; however, patients may also describe a gradual loss or complete anosmia years in duration. Olfaction usually returns, especially in the case of CRS with polyps, with aggressive medical treatment often including systemic steroids. However, inflammation directly involving the olfactory mucosa in patients with CRS has been demonstrated in nasal biopsies, (28–30) and a resulting permanent form of smell loss can occur that is eventually unresponsive to steroids. This CRS-related permanent olfactory loss has been associated with the finding of apoptotic cells within the olfactory epithelium (31) and supports the prudence of aggressive medical and/or surgical management of this disease in order to prevent long-term damage.

Occasionally, patients will present with a history of never experiencing smell, a condition known as congenital anosmia. Their loss is usually recognized through experiences with family or friends or through observation by their parents that they cannot smell a strong odor that others in the same vicinity smell. Although anosmia to specific odors has been identified, patients usually present to physicians with complete anosmia and have no other associated medical conditions. However, a subset of congenital anosmia is associated with Kallmann syndrome (hypogonadotrophic hypogonadism) in which a delay in sexual development can occur, and therefore early recognition of the syndrome is important to allow for hormone replacement therapy. Therefore, pediatric patients presenting with congenital anosmia should be observed for any evidence of delay in development. Mutations covering six genes have

been identified that are associated with Kallmann syndrome and genetic testing can be performed, but genetic testing currently has a sensitivity of only 30% (32,33). Clinical suspicion based on associated findings such as microphallus and/or cryptorchidism in males, hearing loss, or renal agenesis should prompt further workup. An MRI can be obtained to identify agenesis of the olfactory bulbs and rectus gyrus and loss of olfactory sulcus, however, a discussion with the patient's pediatrician and referral to an endocrinologist and/or geneticist is advised. A recent description of a rare congenital smell loss associated with the absence of pain reception in humans has been described that relates to a defect in a voltage-gated sodium channel and may provide insight into more common forms of congenital anosmia (34). Congenital smell loss associated with hypoplastic or absent olfactory bulbs has also been associated with CHARGE syndrome, (35) but other associated deficits other than smell loss are more apparent in this syndrome and the disorder is recognized at an early age.

A different form of congenital anosmia or long-standing smell loss has been identified relating to anatomic narrowing of the olfactory clefts from large concha containing middle and/or superior turbinates. These patients have severe hyposmia or anosmia and are refractory to oral steroids and surgical opening of the olfactory cleft (36,37).

Smell loss can be an early symptom of neurodegenerative diseases such as Alzheimer and Parkinson disease. Schizophrenia has also been associated with smell disorders resulting in difficulty with identification of odors. Environmental toxins associated with smell loss include prolonged industrial exposure to agents such as cadmium, mercury, and formaldehyde (38). Over-the-counter topical zinc nasal spray for treatment of URI has been implicated in causing smell loss in a small percentage of people. Clinically, these patients describe intense nasal burning after use and rapid onset of anosmia (39,40). Although impossible to prove that the smell loss did not develop from the URI, the history of zinc application in humans and animal studies with zinc gluconate suggest a toxic effect on the olfactory neurons (41). The U.S. Food and Drug Administration (FDA) has now advised consumers to stop using zinc-containing nasal products because of the risk of anosmia.

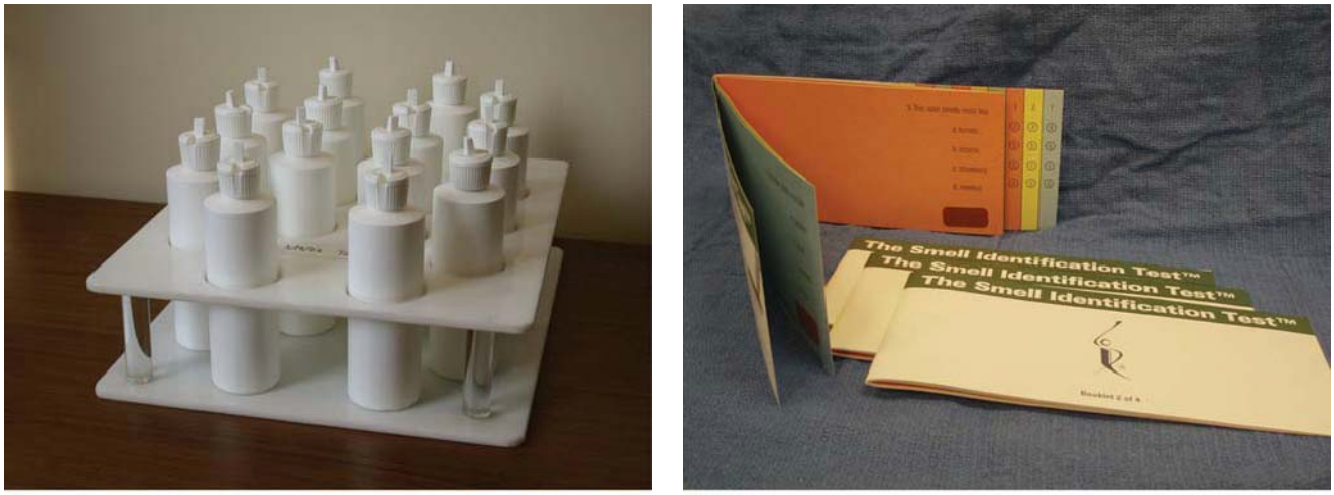
Iatrogenic smell loss frequently occurs with craniofacial resections, but may also occur with commonly performed nasal and sinus procedures. Kimmelman demonstrated mild hyposmia in 32% of patients undergoing an ethmoidectomy, polypectomy, Caldwell-Luc procedure, nasal fracture reduction, rhinoplasty, or septoplasty and anosmia in 1% (42). Damm et al. (43) reported a decreased smell in 20% of patients undergoing septoplasty and turbinate reduction with no reports of anosmia, while 80% improved their olfactory function. Given the alteration and trauma of the nasal mucosa during these surgeries and potential for scarring, it is prudent to include smell loss as a potential complication in preoperative discussion of all nasal–sinus procedures.

EVALUATION

By far, the most useful portion of the evaluation of patients in determining the etiology of smell loss is obtaining a detailed history. Clues as to surrounding circumstances can point to a source of the disorder, and timing can also provide prognostic information. For the most common forms of smell loss, events leading to the smell loss are often obvious. Severe traumatic head injuries preceding a loss of smell are usually brought up by patients without questioning, but patients with anosmia should be asked about any head injury, even mild cases not requiring hospitalization. Traumatic olfactory loss is sudden but often not immediately noticed by the patient because of associated cognitive impairment (44). Sudden onset of smell loss also occurs with URIs. Patients describe a bad "cold" or flu with the usual nasal stuffiness, but with resolution of the associated symptoms, the smell loss remains. These patients are usually very specific in the timing of their smell loss. A report of fluctuation in ability to smell should alert the physician to CRS with polyps as the most likely cause. Associated chronic symptoms of nasal obstruction and drainage are typically present in CRS, and patients typically describe improvement of smell with previous administration of oral steroids for a brief period of time. Many other forms of smell loss described above tend to occur in a more gradual progression. With idiopathic smell loss, patients frequently report a change in the flavor of food over time and are unable recall a specific time of onset or any related event. Smell loss associated with neurodegenerative disorders also present as a gradual onset, and questions regarding memory and cognitive function should be asked in these patients. In the rare case of a nasal mass presenting with gradual smell loss, patients usually complain of unilateral obstruction and often epistaxis. Intracranial masses rarely present with a smell disorder alone, and concomitant diplopia, vision changes, and motor/sensory dysfunction point toward a central cause of anosmia. A complete review of past and current medical conditions, previous surgeries, and list of medications is required in the comprehensive evaluation of smell loss. A complete social history may reveal occupational exposures to olfactory toxins or uncover illicit nasal drug use, such as cocaine.

The physical exam in evaluation of smell disorders includes a thorough head and neck examination with assessment of cranial nerve function. It is important to avoid excessive manipulation of the nose or application of nasal anesthetic agents prior to olfactory testing in order to avoid altering normal responses. Following olfactory testing, particular attention should be given to the nasal airway and possible obstructive causes. Anterior rhinoscopy alone is insufficient in identifying obstructive lesions or polyps (45). Nasal endoscopy with careful inspection of the olfactory cleft for evidence of polyps, mucosal edema, infection, scar formation, or neoplastic lesions is mandatory for evaluating most olfactory disorders.

OLFACTORY TESTING



A thorough evaluation of patients with smell disorders includes olfactory testing and helps to determine the severity of the loss. Usually patients are able to recognize changes in their olfactory ability (46), but testing can often assure patients that residual function remains and even recognizes normal function in some overly-concerned patients. It can also provide a baseline measure to compare with postintervention testing, and in some cases, it can help identify malingering, although given the subjective nature of the tests, most conventional testing can be manipulated by patients if they understand the testing format. Many available olfactory tests can be modified for unilateral use to determine asymmetry in function.

Olfactory testing can be divided into psychophysical and electrophysiologic testing. Electrophysiologic tests include electro-olfactograms, which use electrodes to record field potentials during stimulation, and odor event-related potentials, which measure EEG changes during odor stimulation. Currently, these tests are restricted to research centers and are not accessible to most clinicians (47).

Psychophysical tests are more common in clinical practice, many of which are easy to use and the results can be compared to known population standards (Fig. 24.2). Threshold tests measure the ability to detect an odor (such as butyl alcohol) at the lowest concentration compared with a blank (48). Although this testing provides a pure assessment of the ability to detect presence of an odor, it is time consuming and dependent on a knowledgeable administrator. Identification tests determine the ability to correctly identify multiple presented odors. Occasionally, it is incorporated with threshold tests to provide a global assessment of useful olfactory ability. The Sniffin' Sticks test is an example of such a combined test that is widely used throughout Europe. It comprises multiple odor-impregnated felt-tipped pens that allow tests for detection threshold, identification, and discrimination. A composite score is calculated and compared to normative data (49). It too requires a test administrator and can be time consuming. Probably the most widely used test of olfactory ability is the University of Pennsylvania Smell Identification Test (50). This test is commercially marketed as the Smell Identification Test (SIT, Sensonics, Haddon Heights, NJ, USA). It is a self-administered test that utilizes microencapsulated beads that release an odor with scratching. Subjects are required to choose odors from a list of four possibilities. The test correlates well with odor threshold testing and has been extensively studied. The lack of requirement for a test administrator allows the physician to see other patients and frees up ancillary office personnel making this test very popular in the clinical setting. Cultural bias may be a problem with the standard 40-item test, but a Cross-Cultural SIT has been created with odors recognizable across multiple cultures (51) and culture-specific modifications to other common smell tests have also been developed.

IMAGING STUDIES

Because a detailed history provides the underlying etiology of olfactory disorders in the majority of cases, imaging studies are usually not needed. A clear history of

A B

Figure 24.2 Olfactory tests. **A:** The butanol threshold test consists of a series of progressively stronger butanol dilutions (outer 10 bottles) and blank controls (center four bottles). Patients are asked to identify the bottle containing butonal after smelling a puff of air squeezed from the dilution and a blank. The concentration consistently identified is compared with what responses are known for the normal population and for those with olfactory loss. (Photo courtesy of R. Costanzo, VCUHS Smell and Taste Disorders Center, Richmond, VA.) **B:** The 40-item SIT (Sensonics, Inc., Haddon Heights, NJ) consists of 40 scratch-and-sniff samples matched with the names of four possible odors the patient can choose from. The number of correct responses correlates with the degree of olfactory ability.

URI-related anosmia with absence of findings on physical exam requires no further imaging studies, although they are commonly obtained to rule out an intracranial mass and usually for medical–legal reasons (52). A sinus computed tomography (CT) is helpful for the assessment of CRS and obstruction of the olfactory cleft. In cases where the olfactory cleft cannot be visualized with nasal endoscopy and there is no evidence of CRS on history or exam, a CT scan may be useful to rule out anatomical narrowing of this region due to obstruction from large middle and superior turbinate conchas (36). Patients with traumatic head injury and loss of smell commonly present with multiple imaging studies that were performed in the acute setting. These images can be reviewed to look for extent of intracranial damage to the frontal lobes and olfactory bulbs, but the ability to identify olfactory axonal damage due to shearing forces alone cannot be visualized with current methods (53). There appears to be an associated loss of olfactory bulb volume as measured by magnetic resonance imaging (MRI) in many forms of olfactory loss, but this significance is mostly of research interest (54–56). Similarly, functional MRIs are currently used for research purposes without a clear role in the clinical setting. We reserve ordering MRIs when the olfactory disorder occurs (a) in the absence of a clear etiology, (b) with an unusual presentation, (c) under suspicion of intracranial lesion based on history and exam, (d) with suspicion of a neurodegenerative process, or (e) in congenital anosmia for assessment of the olfactory bulbs and gyrus rectus.

PHANTOSMIA/DYSOSMIA CONSIDERATIONS

Anosmia and hyposmia refer to quantitative changes in perception of smell intensity. Qualitative olfactory changes related to perceived distortions of inhaled odorants are called parosmia while the perception of smell when there is no odorant in the environment is known as phantosmia or olfactory hallucination. Hallucinations almost always are short-lived events (seconds), may precede a seizure, and may be associated with electroencephalography (EEG) abnormalities. Phantosmia is a type of qualitative change that is almost always associated with a loss of smelling ability. In a survey of 193 patients with olfactory complaints, Landis et al. (57) noted that patients with parosmia frequently have a close temporal history of head trauma or URI, while those patients with phantosmia have no such related etiologic association. Both parosmia and phantosmia often start for no apparent reason, and tend to affect females more frequently.

Parosmic patients can have the distortion intermittently or continuously. Phantosmics typically have a history of bad smell perceptions lasting only a few minutes in the beginning, but with a progression over months to having daily episodes, often lasting hours. Some phantosmia patients can stop the phantom smell with single or bilateral nostril occlusion, while others cannot (58).

Parosmia patients almost always say that the distortion is unpleasant, and use words like "rotten" or "chemical." Phantosmia patients also typically have unpleasant distortions, like "burned rubber" or "spoiled food." In one study of the natural history of these qualitative disorders, the authors found that after an average of 12 months, almost a third of the parosmic patients reported relief, whereas about half of the phantosmic patients lost their phantom smell (59). In another study looking at the 5-year result for phantosmia, about one-third lost the bad smell, and about one-fourth had improvement. Less than 5% were worse (60).

TREATMENTS

Reliably effective treatment for quantitative olfactory losses is only available for the conductive type where odorant molecules cannot physically access the olfactory receptors. In this conductive group, which includes patients with nasal polyps and nasal mucosal edema due to allergies, treating the inflammation with saline lavage, oral or topical steroids, antihistamines, antibiotics, or surgery can be very effective.

For neural quantitative losses, there are generally no effective therapies. There is no documented return of smell in patients with complete congenital olfactory loss. With some types of congenital olfactory loss, however, immature olfactory neurons have been found on biopsy, and theoretically these conditions could be improved (61). For the two most common types of neural losses, post head trauma and URI-related loss, there is no predictably effective therapy. One study from Germany showed some improvement in this group with oral prednisone therapy at 40 mg tapered over 21 days (62). We have been unable to duplicate their success with this therapy, and the side effects of the prednisone on the patient must be considered. In a more recent publication, this same group does not mention this prednisone therapy (63). Other forms of therapy such as zinc, alpha-lipoic acid, and theophylline have been suggested, but controlled trials have either shown lack of efficacy (as with zinc) or provided insufficient data to show conclusive results.

It is sometimes difficult to determine whether an olfactory loss has a conductive or neural etiology. Oral steroid administration is useful in distinguishing between a conductive loss that will improve as opposed to a neural loss that will not respond (45). There are, however, patients who have open nasal airways to the olfactory area, but yet only have olfactory ability while on oral steroids (64).

Olfactory training has been recently touted as an effective therapy for those who have some remaining olfactory ability (hyposmia, not anosmia). Daily exposure to strong

odorants like rose, cinnamon, lemon, or cloves has been shown to have some beneficial effect (65). Encouragement for continued use or active practicing should be counseled to those with smell loss since there appears to be a relationship with recovery to some degree.

Qualitative changes in olfaction are typically more bothersome to patients, and its treatment is less well known. As stated above, both parosmias and phantosmias typically resolve in 11 months (23). Although these olfactory distortions typically require some peripheral input to the brain, the smell perception is likely produced in the olfactory bulbs or central brain. We have found that therapy can be directed to both places. Because nostril occlusion can sometimes relieve the unpleasant odor, we have had some success with the patients instilling saline drops in their nostril(s) while kneeling with their head on the floor. This likely occludes the upper nasal airways due the surface tension of the liquid. Olfactory relief experienced from applying these drops can last minutes, to hours, to days. In more severe cases, we have had some success treating olfactory distortions with neurologically active medications like gabapentin, pregabalin, or anti-depressants, although unpleasant side effects limit the usefulness of these medications. Finally, for those rare patients severely affected by these qualitative olfactory changes refractory to more conservative approaches, the endoscopic removal the olfactory epithelium may be beneficial and is associated with less morbidity than olfactory bulb resection through a craniotomy (66).

Counseling to protect the anosmic or hyposmic patient is an important responsibility of the physician. Patients with olfactory loss must employ the use of smoke and natural gas detectors in their homes and offices. If possible, converting to an "all electric" home would be a good option. Educating patients' family members so that they are able to inform the patient if the milk in the refrigerator smells foul are extra safeguards the anosmic patient should practice. If the patient lives alone it is particularly important to use proper refrigeration and storage techniques and remove food at their expiration dates.

Quality of life remains forefront in these patients' minds as olfaction gives them the ability to appreciate food, flavor, etc. In this respect, training to appreciate remaining sensory modalities such as texture of food, color, pungency, residual taste, and mouth sensation is beneficial. Additionally, in patients with hypsomia, training the patient to think about the proximity of the smell and intensify the smell by bringing it closer offers value (67). Likewise, encouraging patients to increase food options and trials of different foods is warranted. Adding hot sauces or eating Asian or ethnic foods may better stimulate the trigeminal nerve promoting additional sensation. The use of excess sweeteners or salt is a natural adaptation by many patients with smell loss, and they need to be aware of the detrimental health effects that can result.

HIGHLIGHTS

- Disorders of smell are not infrequent and have a significant impact on quality of life for those who are afflicted.
- Olfactory receptor neurons are unique in their direct connection to the brain and the regenerative capacity of the olfactory epithelium to replace them throughout the life of the organism.
- URIs, head trauma, CRS, and aging are the most common identifiable etiologies for smell loss. In many cases, a cause for smell loss is never identified.
- A careful history and nasal endoscopy are crucial in the evaluation of patients complaining of smell disorders.
- Validated tests of smell are available for use by all physicians and allow for a subjective assessment of the degree of impairment.
- Besides olfactory loss related to CRS, treatment options and effectiveness for other common forms of smell loss are limited.
- Phantosmia and parosmia commonly occur with olfactory loss, but usually resolve spontaneously.
- Physicians evaluating patients with smell disorders need to discuss hazards associated with smell loss and potential dietary effects such as decreased nutrition and effects of increased salt or sugar intake.

Immunology and Allergy

25

Mohamad Raafat Chaaban *Robert M. Naclerio*

Understanding immunology is fundamental to understanding the pathophysiology, diagnosis, and treatment of many diseases. Allergic rhinitis (AR), with its symptoms of itch, sneeze, rhinorrhea, and congestion, is a classic example of an immunologically mediated disease. We focus on understanding the immunology of AR, which provides broader insights into the immunology of other disease processes that are important to otolaryngologists.

The prevalence of allergic disease in the United States is 20%, and appears to be increasing (1). A nationwide survey published in 2006 showed that 54.6 % of people in the United States tested positive for at least one allergen (2), highlighting the fact that many more people have positive allergy tests than have AR.

AR affects both children and adults, compromising their quality of life (3). The symptoms are either seasonal or perennial in nature. AR (4) is uncommon before the age of 5 (5,6) with the peak incidence occurring between 17 and 22 years (7).

The profound economic impact of allergy is also increasing. Between 2000 and 2005, the cost of treating AR almost doubled from $6.1 billion to $11.2 billion, with more than half of this money spent on prescription medications (8). Costs related to lost productivity and missed work, and health care costs incurred by exacerbation of coexisting medical conditions caused by allergy are more difficult to quantify (9).

THE UNIFIED AIRWAY

In the past several years, there have been some interesting developments in the field of immunoglobulin E (IgE)-mediated diseases. Several studies have shown pathophysiologic parallels between AR and asthma after challenge with antigen. These include hyperresponsiveness to irritants, cell types recruited to sites of inflammation, cytokines produced (10,11), and adhesion molecules expressed after challenge (12).

Increased recognition of the link between the upper and lower airway has led to various terms for respiratory disease involving both, including: "the unified airway," "the united airway," "chronic allergic respiratory syndrome," and "allergic inflammatory airway syndrome" (13). Although the linkage has not been fully characterized, there is speculation that a bidirectional linkage exists. Rhinitis can affect asthma by way of the nasobronchial reflex, secreted cytokines, upregulation of circulating cells, or microaspiration (14,15).

In addition to pathologic studies, several studies have shown that AR is a risk factor for the development of asthma, and increasingly so with greater severity of rhinitis (16–18). In a retrospective study of health claims for asthma patients, those patients with concurrent rhinitis doubled their annual medical resource utilization and costs (19).

The clinical practice guidelines for asthma entitled Expert Panel Report 3: Guidelines for the Diagnosis and Management of Asthma, developed by the National Asthma Education and Prevention Program of the National Heart, Lung and Blood Institute released in August 2007, stated: "The Expert Panel recommends that clinicians evaluate patients who have asthma regarding the presence of rhinitis/sinusitis diagnosis or symptoms. it is important for clinicians to appreciate the connection between upper and lower airway conditions and the part the connection plays in asthma management" (20). Treatment of rhinitis may enhance asthma control (21–24), and early treatment of allergies may prevent the development of asthma (22–24).

Interestingly, patients treated with low-dose fluticasone propionate nasal spray had a significantly lower risk of experiencing an asthma-related hospitalization and incurred lower asthma-related and overall health care costs

compared with those who used montelukast (25), further demonstrating the connection between the upper and lower airways.

THE IMMUNE RESPONSE

The immune system identifies and destroys elements foreign to the body while recognizing and protecting self-components. The inability to properly recognize "self" results in the broad class of diseases known as autoimmunity disorders. Many autoimmune disorders affect the ear, nose, and throat. For example, a cell-mediated immune response is thought to be the etiologic precipitant for the development of relapsing polychondritis, a rare multisystem autoimmune disease, which targets cartilaginous tissues and often involves the nose. Wegener granulomatosis, a vasculitic disease that can be accompanied by ulceration of the nasal mucosa, is also thought to have an autoimmune etiology. Evidence points to auto-reactive T cells aiding in the production of antineutrophil cytoplasmic antibodies, which may be pathogenic in cell-mediated induced injury.

INNATE AND ADAPTIVE IMMUNITY

Innate Immune System

The innate immune system is the first line of defense against foreign substances. It comprises both physical barriers and an array of receptors and antimicrobial compounds. The sinonasal barrier comprises ciliated epithelial cells, subepithelial glands, goblet cells, and the mucus blanket. This epithelium provides a barrier via tight junctions that prevent passage of pathogens across the mucosal surfaces and mucociliary transport to eliminate pathogens trapped in secreted mucus. Nasal glandular products such as lactoferrin, defensins, and lysozyme are the initial defense against infection and function irrespective of prior exposure to the pathogens. Impairment of the innate immune system provides one theory as to how inflammation leads to the development of chronic rhinosinusitis (CRS) (26).

The cells associated with innate immunity include neutrophils, monocytes, mast cells, eosinophils, basophils, and dendritic cells (DCs). These cells are activated in the presence of microbes and work to rid the body of infection. They use pattern recognition receptors (PRRs) found on their surfaces, intracellular compartments and secreted in the bloodstream to opsonize bacteria, activate coagulation and complement cascades, induce phagocytosis and apoptosis, and implement proinflammatory signaling pathways (27).

There are several classes of PRRs: Toll-like receptors (TLRs), RIG-I-like receptors, Nod-like receptors, and C-type lectin receptors (27). PRRs recognize highly conserved DNA sequences that are necessary for the survival of many microorganisms. These highly conserved sequences, known as pathogen-associated molecular patterns (PAMPs), include peptidoglycan and lipoteichoic acid from gram-positive bacteria, lipopolysaccharide (LPS) from gram-negative bacteria, and RNA from viruses. The responses of the innate immune system against the PAMPs signal the adaptive immune system to develop memory and subsequent longer-lasting immune responses. TLRs, first described in 1994, are the most studied of the various PRR classes. They are transmembrane glycoproteins with an extracellular N-terminal leucine-rich domain and an intracellular C-terminal domain, which is itself known as Toll/interleukin (IL-1) receptor (TIR) because of its homology to IL-1 (28).

Recognition of the various PAMPs by TLRs on the surface of monocytes, macrophages, DCs, and mast cells initiates inflammatory responses, which induce cytokine signaling that can be Th1 or Th2. This signaling can be categorized as either myeloid differentiation primary response (MyD88)-dependent (Fig. 25.1), which is used by all TLRs except for TLR3, or TIR containing adaptor-inducing interferon (IFN)-γ-dependent pathways (29). TLRs respond to specific conserved sequences or to molecules present on invading microbes; for example, TLR4 responds to lipid A, a component of LPS, whereas TLR3 recognizes double-stranded RNA. Inflammatory cells express different classes of TLRs, depending on their lineage and maturity (30). The spatial distribution of TLRs ultimately determines the microbes they encounter and whether these elements are recognized as being self or nonself (31,32). Some TLRs are expressed on the cell surface, whereas others are expressed intracellularly within endosomes (Table 25.1).

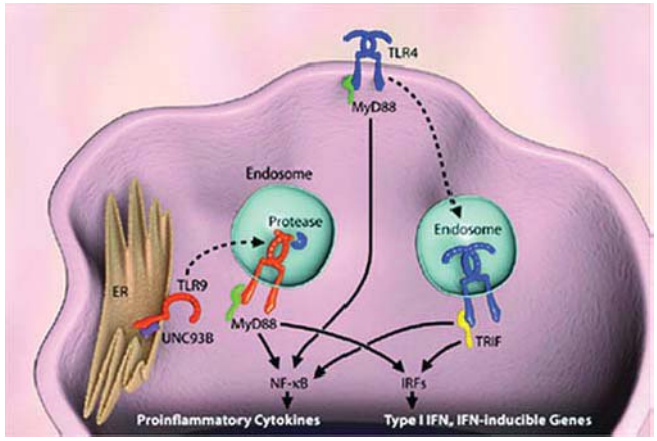

Figure 25.1 Cell biology of TLR signaling. TLR4 is located at the plasma membrane and translocates to the endosomal compartment on stimulation. Although MyD88-dependent signaling occurs without endosomal translocation of TLR4, TIR-domain-containing adapter-inducing interferon-β (TRIF)-dependent signaling requires dynamin-dependent translocation. In a resting cell, TLR9 is localized at the endoplasmic reticulum (ER), but is translocated to the endosome on stimulation, where a protease or proteases cleave TLR9. IRF, interferon regulatory factor; TRIF, Toll/IL-1 receptor domain containing adaptor-inducing interferon-β. (Adapted from Kumagai Y, Shizuo A. Identification and functions of pattern-recognition receptors. *J Allergy Clin Immunol* 2010;125:985–992.)

TABLE 25.1 SUMMARY OF TLRS

	TLR Location	PAMPs Recognized
TLR1	Cell surface	Triacyl lipopeptides (bacteria and mycobacteria)
TLR2	Cell surface	Hemagglutunin protein (viruses), peptidoglycan, and LTA (Gram-positive bacteria), lipoarabinomannan (mycobactria)
TLR3	Endosome	ssRNA, dsRNA viruses
TLR4	Cell surface	LPS (Gram-negative bacteria), glycoinositolphospholipids (*Trypanosama*), mannan (*Candida*), fusion protein (respiratory synctial virus)
TLR5	Cell surface	Flagellin, an important protein in bacteria motility, adhesion, and invasion
TLR6	Cell surface	LTA (Gram-positive bacteria), zymosan (*Saccharomyces*)
TLR7	Endosome	ssRNA viruses
TLR8	Endosome	ssRNA viruses
TLR9	Endosome	dsDNA viruses, unmethylated CpG motifs
TLR11	Cell surface	Profilins from toxoplasmosis gondii, uropathogenic *Escherichia coli*

dsDNA, double stranded deoxyribonucleic acid; LPS, lipopolysaccharide; LTA, lipoteichoic acid; PAMP, pathogen-associated molecular patterns; ssRNA, single stranded ribonucleic acid; TLR, toll-like receptor. Adapted from Ooi EH, Psaltis AJ, Witterick IJ, et al. Innate immunity. *Otolaryngol Clin N Am* 2010;43: 473–487.

Natural killer (NK) cells originate in the bone marrow and participate in the innate immune system. NK cells simultaneously express both T-cell markers (CD3, T-cell receptor [TCR]-αβ) and NK cell markers (CD56, CD16, CD95, and CD178) (33). A large fraction of NK cells are referred to as invariant NK cells, and they are characterized by the expression of a single unique TCR-α rearrangement. Upon activation of NK cells, they are capable of rapid and substantial production of cytokines, including IL-4, which is an important cytokine in allergic pathogenesis (34).

NK cells were first known for their capability to lyse tumors without any prior priming or immunization. They have been shown to have diverse functions ranging from secreting cytokines such as INF-γ, TNF-α, and granulocyte monocyte-colony stimulating factor (GM-CSF) and chemokines (lymphotactin, RANTES (Regulated upon Activation, Normal T-cell Expressed, and Secreted), and macrophage inflammatory protein [MIP]-1α/MIP-1β) after activation (35) to serving as intermediaries between the innate and adaptive immune systems.

NK cell precursors express IL-2 receptor once they commit to the NK lineage. As they mature, further receptor diversity is procured, and the mature NK cell exhibits specific major histocompatibility complex (MHC) receptors, including 2B4, CD38, CD7, and killer-cell immunoglobulin (Ig)-like receptor. Upon completion of maturation, NK cells migrate to the peripheral blood and congregate in the spleen, lymphoid organs, lungs, and liver. There are two different types of NK cells—those that participate in killing and those that focus on cytokine production (36).

Another feature of innate immunity is the complement system. The complement system is the primary humeral mediator of antigen–antibody reactions. Initially, complement was thought to play a major role only in innate immunity against invading pathogens. It was discovered subsequently that the complement system plays an important role in the adaptive immune system by being involved with both T and B cells (37). It has also been shown to play a role in tumor growth (38), tissue regeneration, and in diseases like hemolytic uremic syndrome and age-related macular degeneration (39).

The complement consists of at least 30 chemically and immunologically distinct proteins, which can interact with each other, with antibodies, and with cell membranes. The proteins exist either as soluble in the blood or as membrane-associated. There are three routes by which the complement system is activated: the classical pathways, the lectin pathway, and the alternative pathway. All of the pathways converge at C3 (which is the most abundant complement protein found in the blood), resulting in the formation of activation products and the membrane attack complex (C5b-9) (40).

The biologic activity of complement is manifested in three ways. First, certain complement proteins bind to or opsonize foreign particles. Specific cellular receptors for these complement proteins then mediate the binding and uptake of the opsonized particles by polymorphonuclear leukocytes and monocytes. Second, the small fragments of proteolytic cleavage from complement proteins diffuse readily, and they can bind to neutrophils and macrophages, causing chemotaxis and cell activation. Similar receptors on lymphocytes and antigen-presenting cells bind antigen–antibody complexes and enhance specific immune responses such as phagocytosis and clearance of apoptotic cells. Third, complement causes lysis by the

insertion of a hydrophobic "plug" into lipid-membrane bilayers, allowing osmotic disruption of the target cell. Deficiencies in complement lead to severe infectious or autoimmune diseases.

Complement may play a role, in the nasal mucosa, in an immediate-type hypersensitivity reaction by stimulating mast cells. Studies of asthma have implicated increases of anaphylatoxins C3a and C5a at sites of inflammation after segmental allergen provocation of the bronchus in asthma patients (41), which can contribute to cellular recruitment of inflammatory cells.

Another important player in the innate immune response is the numerous antimicrobial peptides that are expressed in the sinonasal and lower airway epithelium (26). These include lactoferrin (42), lysozyme (43), cathelicidin (44), defensins (45), SP-A and -D (surfactant protein) (46,47), acid mammalian chitinase (47), collectins (48), serum amyloid A (49), and secretory leukocyte proteinase inhibitor (50). The most abundant of the antimicrobial peptides in nasal secretions are the lysozyme, lactoferrin, and secretory leukocyte proteinase inhibitor (51). In addition to being referred to as endogenous antibiotics by being secreted in response to microbes, these peptides also play a role in activating or suppressing effector cells of the innate and adaptive immune system. Human cathelicidin, LL-37, is chemotactic for neutrophils, monocytes, and T cells (52). It has also been shown that SP-D can cause a shift from a Th1 to a Th2 cytokine response, inhibit lymphocyte proliferation (53), and regulate DC responses (54).

The defensins, composed of α-defensins and β-defensins, are expressed on cells such as neutrophils, monocytes, epithelial cells, and paneth cells (55). Paneth cells, which are located at the base of intestinal glands, secrete α-defensins when exposed to bacteria and thus contribute to the gastrointestinal barrier. Degranulation of cells that express defensins occur in a dose-dependent manner as part of the host defense in response to infection at epithelial surfaces (55). It is well known that phagocytes and leukocytes are recruited to sites of infection via chemotactic factors (56). Defensins induce chemotaxis of the immature DCs to the sites of infections (56).

The mRNA of HD5, an α-defensin, is expressed in variable amounts in nasal epithelial cells (57). β-Defensins in mice induce maturation of DCs via TLR4 (58). Because DCs are involved in both antigen (Ag)-specific immune responses and Th1/Th2 polarization, defensins may contribute to interactions between the innate and the adaptive immune system via their influence on DCs. Cathelicidin is an antimicrobial protein expressed by epithelial cells, monocytes, NK cells, mast cells, and γδT cells. LL-37, a cathelicidin peptide, participates in host antimicrobial immunity by recruiting phagocytes, immature DCs, and T cells to sites of inflammation (52). Both LL-37 and human β-defensin-2 cause mast cell degranulation, with consequent histamine release (59). Eosinophil-derived neurotoxin is implicated in antiviral roles and has been shown to play a role in DC development, and like defensin, it may also play a role in bridging of the innate system with the adaptive immune system (60).

Other roles of the antimicrobial peptides have been postulated. Biofilms, which are implicated as a possible cause of CRS (61,62), are organized communities of microbial cells that are attached to living surfaces and are composed of exopolysaccharide matrix encased in a self-produced exopolysaccharide matrix and attached to an inert or living surface (63). *In vitro*, synthetic Cathelicidin LL-37 shows antibiofilm properties at subbactericidal concentrations when cultured with Pseudomonas aeruginosa (64). In animal models, synthetic LL-37 successfully eradicated biofilm of Pseudomonas sinusitis (65).

Adaptive Immune System

Innate immunity controls and eliminates infection with the help of the complement system, NK cell activation, and TLR activation. If the innate immune system is unable to mount an inflammatory response sufficient to remove pathogens, the adaptive immune response is activated. The adaptive immune system, in contrast to the innate immune system, is highly specific in nature and benefits from gene rearrangement. Developing B and T lymphocytes obtain randomly assembled Ig receptors and TCR from specific gene segments. The variable, diversity, and joining (VDJ) segments that are flanked by recombination signal sequences are recombined with either addition or subtraction of nucleotides, creating immense variability in the receptor (66). Whereas the remodeling process that regulates chromatin accessibility of target gene segments remains unclear, it is evident that these processes tremendously expand the diversity of antigen recognition.

The adaptive immune system utilizes many of the same cells as the innate immune system. One major difference between the two responses is the mode of recognition of antigens. Whereas the innate immunity recognizes microorganisms through components present on their cell walls via broad receptor recognition, the adaptive immune system recognizes specific antigens that are processed and presented by antigen-presenting cells in the context of MHC receptors. In cell-mediated adaptive immunity, priming occurs during the first exposure to antigen by MHC II on antigen presenting cells (APCs) with the help of costimulatory molecules. TCR receptors on the T cell associate with the CD3 receptor and, in turn, activate a series of phosphorylation steps within the cell, resulting in the formation of either CD4+ or CD8+ T cells. Activation of T-helper (Th) cells allows the secretion of many cytokines and mediators which, in turn, activate effector cells such as macrophages. Also, in humeral adaptive immunity, the primed Th cell comes into contact with B cells expressing the same antigen. Interaction between these two cell types and linking of CD40 and CD40L on B and activated Th cells, respectively,

causes B-cell activation and differentiation into antibody-secreting plasma cells (67).

A major difference between the adaptive and the innate immune system is the capability of memory in the adaptive system. Most activated T cells function as effector cells and later undergo apoptosis. Some of them, however, differentiate and persist in the host for many years to provide rapid protection on subsequent antigen exposure. The exact mechanism by which certain subsets of T cells become memory cells, and under what signaling conditions, is under investigation.

THE LINK BETWEEN THE INNATE AND ADAPTIVE IMMUNE SYSTEMS

There has been increasing evidence regarding the cross talk between the innate and adaptive immune responses. TLRs, being part of the innate immunity, play an important regulatory role in the function of antigen-presenting cells (68). It has been found that the signals that spur the induction of the adaptive immune system are many, but ample evidence now suggests that activation of TLRs on APCs results in upregulation of costimulatory molecules that induce type-I INF responses and facilitate APC–T-cell interactions that are necessary for the adaptive immune system (69). In one study, Jang et al. (70) found that IL-6 and IL-10 produced by DCs in response to *Mycobacterium tuberculosis* occurred largely as a result of the contribution of TLR2 responses.

DCs express TLR, which are able to recognize pathogen-derived molecules or endogenous signals released by damaged or dying cells (71). Immunologic tolerance results from exogenous antigen presentation of DCs in the absence of direct PRR stimulation (72). PRRs on DCs also play an essential role in driving the cell production of Th1 and Th17-polarizing cytokines such as IL-12, IL-6, transforming growth factor (TGF-β), and IL-23 (68–71). There is also evidence that DCs can be primed for Th-2 polarization through OX40/OX40 ligand interactions, which are thought to be facilitated by the basophil production of IL-4 (71,72).

TLR activation through several pathways contributes to polarization to Th1 immune responses—leading to the hypothesis that this polarization may prevent Th2 immune responses and allergy. Studies in allergen-challenged TLR4-defective mice showed reductions in airway inflammation with eosinophils, allergen-specific IgE levels, and Th2 cytokine production, compared with wild-type mice (73). TLR activation may also lead to Th2 responses. TLR-2-stimulated DCs *in vivo* produce abundant IL-10, which favors a Th2 response (74). All of these developments have led to hypotheses that TLRs play a role via DCs in linking the innate immune system to adaptive immune deviation in allergy.

Trompette et al. (75) reported on a more intimate link discovered between TLR4 signaling and allergic sensitization to specific antigens. The major allergens of house dust mites are homologs of MD-2, the secreted LPS-binding member of the TLR4 signaling complex. Functional homology suggests that Der p2/LPS may drive airway Th2 inflammation *in vivo* in a TLR4-dependent manner, retaining this ability in the absence of MD-2. These data further suggest that Der p2 tends to generate effector lymphocyte responses because of its ability to activate the innate immune system through TLR4 signaling (76–79). A further understanding of the influence of TLRs on Th1/Th2 is likely to help us better understand the mechanisms of allergy.

Immunohistologic studies on sinonasal biopsy specimens have shown that TLR4 is localized in the submucosal seromucinous glands and the TLR2 in the stroma deep to the epithelial surface (80). Reduced mRNA expression of TLR2 was reported in turbinate tissue biopsies of patients with allergic or non-AR as compared to controls (81). It has also been shown that the TLR2 mRNA expression of TLR3 and TLR4 mRNA was reduced in patients with nasal polyps and with fungal colonization, which may represent a link between fungus and TLR expression in nasal polyps (82).

Another link between innate and adaptive immunity is through the NK cells. They have been found in several studies either to activate DC maturation (83), or they are activated by DCs to increase in numbers, secrete IFN-γ, and then to modulate or, in essence, create negative feedback of the afferent limb of the immune response by killing immature DCs (84). This concept is important in that it suggests a complex interplay of cells in the innate regulation of the immune response by NK cells prior to their activation in the adaptive immune response.

CELLS OF THE IMMUNE SYSTEM

The cells of the immune system are derived from pluripotent hematopoietic cells. They develop along two distinct lineages: the myeloid and the lymphoid. The myeloid stem cell lineage is further divided into granulocytes, megakaryocytes, platelets, and erythrocytes. Granulocytes play an important role in allergic responses as early responders in inflammation; they phagocytose bacterial pathogens and secrete important cytokines.

Pluripotent stem cells also differentiate along the lymphoid stem cell line, of which T cells, B cells, and NK cells are major players in the immune response to allergy (85).

Neutrophils

Blood neutrophils are composed of two interchangeable subpools: the "circulating pool" and the "marginal pool." For the "circulating pool" of neutrophils to reach the site of acute inflammation, they must pass through a series of coordinated steps that include adherence to endothelium, extravascular migration, chemotaxis, membrane recognition, attachment to foreign particles, phagocytosis, fusion of lysosomes, degranulation, and a burst of oxidative metabolism.

Neutrophils are recruited and activated by Th17 cells in either a direct or an indirect way. The direct way is through IL-8 production, and the indirect way is by inducing the production of CSF and CXCL8 (86,87). For their adhesion to the vascular endothelium, they need chemokines and selectins.

Once they reach the site of inflammation, the neutrophils recognize particles by the opsonins attached to them. These opsonins include Igs to which the neutrophils exhibit Fc receptors and the C3b fragment of complement. After phagocytosis, the processes described for mononuclear phagocytes also apply to neutrophils.

In regard to their role in allergy, neutrophils are recruited during the late response to antigen challenge, but they are rarely seen to increase during seasonal allergen exposure, making their role in allergic disease uncertain.

Eosinophils

Eosinophils are produced in the bone marrow from CD34+ hematopoietic precursors. They circulate in the blood and localize to inflamed tissues. Many cytokines are important in the recruitment of eosinophils to sites of inflammation, but the most important are IL-1, IL-5, and TNF (88). Eosinophils possess adhesion molecules (ligands), which assist in their movement toward chemokines such as RANTES, MIP-1α, eotaxin, and monocyte chemoattractant protein-4 (MCP-4), secreted by inflamed tissues (85).

Eosinophil function results from elaboration of a variety of cytokines, proteins, peroxidases, and enzymes. One of these, a major basic protein, is cytotoxic and helminthotoxic. Also elaborated are eosinophil peroxidase, eosinophil-derived neurotoxin, Charcot-Leyden crystal protein, and eosinophil cationic protein (85).

Survival of eosinophils in tissues is based upon their need for several growth factors, such as IL-5, IL-3, and GM-CSF. In the absence of growth factors, they undergo programmed cell death (apoptosis). IL-33 enhances the survival of eosinophils, causes the production of superoxide anion, and activates eosinophils as effectively as does IL-5 (89). Blocking of the receptors of IL-33, namely ST2, reduced the survival of eosinophils and the production of IL-8 (89).

Konya et al. (90) reported that endothelial cell-derived prostaglandin (PG) I-2 attenuated the migration of eosinophils *in vitro*. In addition, upon treatment of the endothelial cells with a cyclooxygenase inhibitor, eosinophil migration and adhesion were blocked. These results suggest that selective PGI-2 receptor agonists might have beneficial effects in allergic inflammation.

Basophils

Basophils are granulocytes that possess high-affinity IgE receptors. They contain histamine and other mediators, including cytokines. They can contribute to anaphylaxis by releasing histamine. They express IL-4, and contribute to allergic reactions at tissue sites such as the nose, lungs, and skin (91,92).

Monocytes

Monocytes originate in the bone marrow from pluripotent stem cells and then are released into the blood. They produce PGs, IFNs, proteases, and cytokines. They play a role in immunomodulation with their expression of histamine H4 receptor, which is involved in the perpetuation of allergic inflammation. Histamine H4 mediates mast cell migration toward CXCL12, which is a constitutive chemokine (ligand of CXCR4 and CXCR7) that is expressed in the skin and in the airway epithelium and plays a significant role in allergic airway diseases (93,94).

Upon migration from the blood into tissues, monocytes mature into macrophages or APCs, which are either dendritic or Langerhans cells interspersed in the epithelial layer of the nasal mucosa and skin. It has been found that this maturation is associated with upregulation of H-1 (histamine) receptors (95). In the proliferation of immature macrophages, mitogens such as CSF, which is produced by fibroblasts, lymphocytes, and monocytes, play an important role. During inflammation, both migration and proliferation increase dramatically (96).

Macrophages are the most abundant immune cell in the airways in the absence of inflammation (96). They play an important role in the initiation and regulation of the immune response by producing Th1-type cytokines (IL-12, IL-18, TNF-α, and IFN-α/β). Macrophages that produce IL-12 increase the bronchial responsiveness associated with eosinophil migration. Macrophages producing IL-1 stimulate T-cell function, and present immune molecules to lymphocytes (97), displaying the same major histocompatibility determinants used by T cells (98). IL-1 increases production of PGs and leukotrienes, which may alter vascular permeability and bronchial tone. IL-1 also induces the production of acute-phase proteins, including complement components, fibrinogen, and clotting factors, and increases the activity of adhesion proteins (e.g., intracellular adhesion molecule [ICAM]-1). Substances chemotactic for macrophages include C5a anaphylatoxin, bacterial products such as *N*-formylmethionyl peptides, and products from stimulated B and T lymphocytes (99).

Also important are substances that inhibit migration away from sites of inflammation: lymphokines (macrophage inhibitory factor and macrophage activation factor) and proteolytic enzymes produced during activation of complement (factor Bb).

The capacity for macrophages to recognize opsonized particles resides in their receptors, which bind the Fc portion of Igs and the C3 components of complement, which facilitate phagocytosis and subsequent killing of ingested microbes and tumors as follows. Particles bound to specific or nonspecific membrane receptors are surrounded

by the macrophage cell membrane, forming phagocytic vesicles. Endocytic vacuoles become secondary lysosomes after fusion with primary lysosomes. Within the lysosomal compartment, the contents are digested at acid pH by more than 40 hydrolytic enzymes. After ingestion of particles, macrophages as well as neutrophils undergo a respiratory burst, observed as a dramatic increase in the consumption of oxygen and activation of a membrane-associated oxidase. This oxidase reduces molecular oxygen to superoxide anion, which, in turn, dismutates to hydrogen peroxide. Superoxide and hydrogen peroxide interact to give rise to hydroxyl radicals and singlet oxygen. These reactive metabolites of oxygen exert antimicrobial and antitumor effects.

Another group of effector molecules synthesized by macrophages includes nitric oxide and reactive nitrogen intermediates. The macrophage itself is protected from these oxygen metabolites by its glutathione peroxidase and catalase. Numerous soluble agents, including antigen–antibody complexes, C5a, ionophores, and tumor promoters, can trigger the respiratory burst without phagocytosis (97).

Lymphocytes

T Lymphocytes

The cells primarily responsible for immune recognition are lymphocytes, which have surface-specific receptors for antigenic determinants of foreign molecules. Certain lymphocytes confer the ability to recognize host cells that are infected with intracellular microorganisms through recognition of epitopes presented on the cell's surface. It is therefore imperative that lymphocytes also retain the ability to recognize self-antigens in addition to foreign elements in order to be effective in targeted destruction.

The T cells make up 60% to 70% of peripheral lymphocytes. They are concentrated in zones where they are likely to meet antigen, namely, the paracortical areas of lymph nodes and of the spleen. They originate in the thymus and participate in cell-mediated immunity. T cells confer high degrees of specificity within the clone, and variability across all T cells through the recombination of the antigen-specific portion of their CD3-TCR. In addition to CD3, T cells have a variety of other surface markers that are important in allergy. CD4 and CD8 are markers on certain subsets of T cells and enhance the signal that occurs when a T cell comes into contact with an appropriate antigen-MHC complex borne by APCs. A second signal is provided via CD28 that interacts with the costimulatory molecules B7-1 and B7-2 that are present on APCs (97).

When the T cells leave the bone marrow, they leave as the pre-T cells CD4-CD8-DN (double negative) cells. It is not until gene segment rearrangements occur during their maturation that they will have a gene coding a full-length TCR protein. From a pre-T cell, sequential rearrangements of two TCR genes leads to surface expression of an αβ or γδ TCR (100). Double positive T cells, that is, T cells that are both CD4 positive and CD8 positive, only survive if they are able to recognize self-antigens presented in that particular individual's MHC molecules. They thus undergo positive selection. The T cells then drop either the CD4 to become CD8+, or cytotoxic T cells, or retain only the CD4+ molecules, to become CD4+ T helper cells. Deeper in the thymus, negative selection occurs, which selects for T cells that bind too strongly to self-antigens and causes these cells to apoptose. These two selection processes allow for tolerance of self by the immune system as well as positive selection of T cells that are able to recognize peptides displayed in that individual's unique MHC I and MHC II molecules.

γδ T cells, which only comprise 2% of T cells, are thought to play a role in mucosal immune defense because they accumulate in epithelial sites of inflammation and in some mouse models, γδ T cells do play a role in allergic inflammation (101), however, evidence for the role of γδ T cells in allergic inflammation is conflicting.

CD4+ T Cells

CD4+ T cells interact with cells in the context of MHC-II protein, which is present on APCs. These cells develop into Th1 and Th2 cells. Upon leaving the thymus, CD4+ cells enter the lymphoid organs, where their naïve TCR receptor comes into contact with antigen-MHC complexes on APCs. The type of APC, the costimulatory molecules produced, in addition to the local cytokine environment, all play a role in determining whether the Th cell will become a Th1 or Th2 cell (102). Th1 and Th2 cells are only able to be distinguished from each other by the substances they produce. Th1 cells secrete IFN-γ, IL-2, TNF-α, and TNF-β, which are important for eliminating intracellular pathogens. In contrast, Th2 cells secrete IL-4, IL-5, IL-6, and IL-13, which are important for the elimination of extracellular organisms.

It is also important to mention that peptides are not the only target of T-cell response, as T cells recognize a variety of lipid antigens by means of a family of nonpolymorphic genes (CD1) (103) that evolved to present lipids and glycolipids to the mammalian immune system (104,105). CD1a is expressed on DCs and macrophages. The CD1 protein is implicated in pollen capture and processing (106,107). It is speculated that this recognition by CD1+ DCs and CD1-restricted T cells is involved in the rapid handling of the foreign inhaled grain and initiates the allergic response (107).

CD8+ T Cells

CD8+ cells interact in the context of MHC-I, which is present on all cells. The role of CD8+ cells in allergy is not clear, although some studies hypothesized that CD8+ cells may prevent the development of airway hyperresponsiveness (108,109). CD8+ cells secrete cytokines of the Th1 type and function primarily as cytotoxic cells promoting the death of recognized infected cells.

Dichotomous findings with respect to CD8+ cells led to attempts to further characterize the subpopulations of

CD8+ cells. One study showed the different cytokine profiles of CD8 cell subpopulations stimulated by dendritic cell 1 (DC1) and dendritic cell 2 (DC2). Specifically, IL-10 producing-CD8 cells activated by DC2s were presumed to play a regulatory and possibly an immunotolerant role in the immune response (110). CD8 cells are thought to prevent the induction of immune responses early in the sensitization process, but had a limited role once airway sensitization had occurred (111). Other studies point to the homing capabilities of CD8 cells. Those cells that migrate to lymphoid organs are named central memory cells, whereas those that home to nonlymphoid tissue are called effector cells in inflammatory processes. Elucidation of how and when activated T cells commit to memory cell lineage is still unknown. One interesting development is that memory CD8+ T cells are more efficient in TCR signaling and better augment downstream signaling than are naïve or effector cells (112). This supports the finding that symptoms of AR may continue to increase in patients later in the allergy season despite decreasing allergen counts.

T_{reg} Cells

T cells previously called T suppressor cells, are now called T regulatory (T_{reg}) cells. T_{reg} cells are CD4+CD25+ T cells that express the IL-2 receptor marker (CD25). Previously known for taking part in preventing autoimmunity and transplant rejection, they are now recognized as immunomodulators in the Th1/Th2 paradigm. The T_{reg} subset called Tr1 cells (inducible T_{reg} cells) can produce large amounts of IL-10 and TGF-β (113), which can down regulate allergen-specific Th1 and Th2 responses (114).

T_{reg} cells play a role in areas of tolerance. Children who outgrew their milk allergy (called tolerant children) demonstrate significantly higher peripheral T_{reg} cells compared to children who continued to experience allergy to cow's milk (115).

In a cohort study of over 150 children at age 6 from atopic families, CD4+CD25+ T cells were highest during pollen allergy season, which suggests that these cells represent a mixture of regulatory and activated cells (116). Furthermore, in another study, the number of T_{reg} cells to dust mite allergen were found to be similar in both nonatopic and atopic individuals, cautioning against a simplistic view that atopic diseases are caused only by a deficiency of T_{reg} cells (117). T_{reg} cells also play a role in immunotherapy by secreting IL-10 and TGF-β and inducing B cell Ig class switch toward IgA and IgG4 (Fig. 25.2).

B Lymphocytes

B lymphocytes, like T lymphocytes, leave the bone marrow and localize to peripheral lymphoid tissues. They aggregate in follicles within lymphoid organs, where they coordinate the humeral response. When stimulated by antigen via their IgM surface receptors or B cell receptors (BCRs), BCRs associated ligands aggregate to form signaling complexes, whose strength is modulated and propagated via second

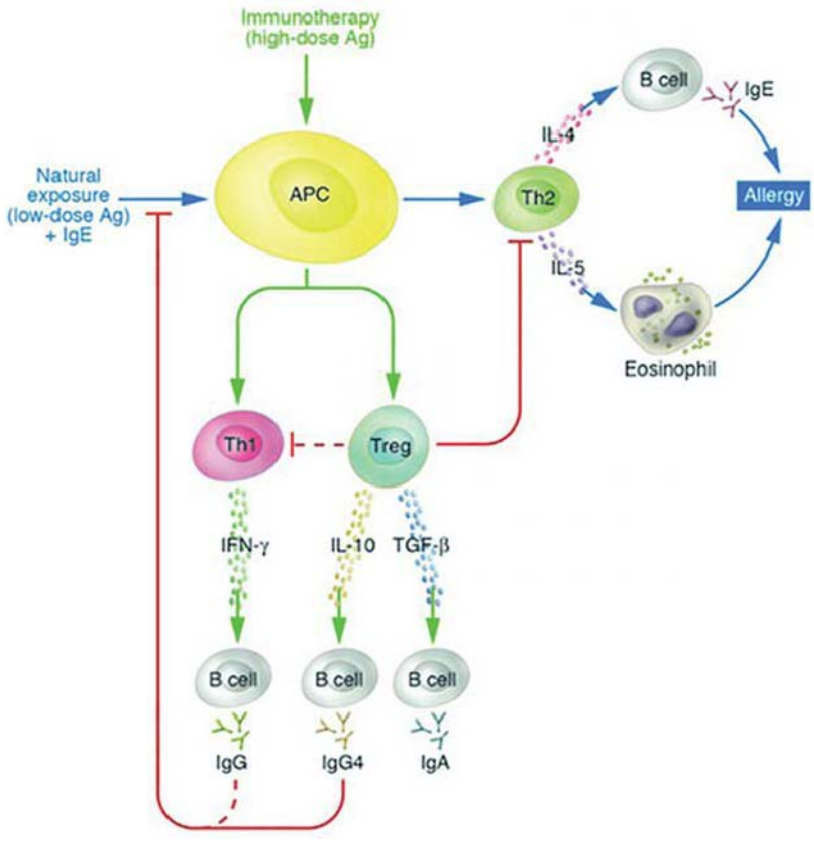

Figure 25.2 Potential mechanisms of conventional allergen immunotherapy. High-dose allergen exposure during immunotherapy results in both immune deviation of Th2 responses in favor of a Th0/Th1 response and the generation of IL-10– and TGF-β–producing CD4+CD25+ T cells, and possibly T_{regs}. IFN-γ–induced activation of bystander macrophages and/or other cells represents an alternative source of these inhibitory cytokines. During subsequent natural environmental exposure to allergens, the activation and/or maintenance of the usual atopic Th2 T cell response is inhibited. Additionally, these cytokines induce preferential switching of B cell responses in favor of IgG and IgG4 antibodies (and possibly IgA antibodies under the influence of TGF-β). IgG may also inhibit IgE-facilitated allergen binding to antigen-presenting cells with subsequent downregulation of IgE-dependent Th2 T-lymphocyte responses. *Blue arrows* represent immune response pathway to natural exposure (low-doses Ag and IgE); *green arrows* represent immune response pathway to immunotherapy (high dose Ag); *red blocked lines* represent inhibition (high-dose Ag); *dotted lines* represent possible means of action not yet proven. (Adapted from Robinson DS, Larché M, Durham SR. Tregs and allergic disease. *J Clin Invest* 2004;114:1389–1397.)

messengers such as diacylglycerol, inositol triphosphate, and intracellular calcium release. B cells differentiate into plasma cells. Plasma cells are responsible for secreting different classes of Igs that mediate humeral immunity. The synthesis of Igs together with heavy chain class switching can occur in the nasal mucosa (118) and be induced in response to allergen exposure (119). IL-4, IL-13, and CD40 are the elements necessary to promote synthesis of IgE and Ig heavy chain class switching in the nasal mucosa. Wise et al. (120) and Durham et al. (121), showed activation of these mediators following allergen provocation. Secondary lymphoid organization can also be seen within nasal polyps (122). Thus class switching can occur outside lymph nodes (123,124), and in the sinonasal tissue.

Dendritic Cells

DCs express receptors such as members of the TLR family that enable them to recognize pathogen-derived molecules or endogenous signals released by dying or damaged cells (125). DCs also express receptors of cytokines like TNFs or IFNs, allowing these cells to recognize a wide spectrum of pathogens like viruses or parasites.

DCs are thought to have two distinct origins. The majority are from a myeloid progenitor, which bears CD11c, CD33, and CD13 cell surface markers and is called myeloid DCs. A smaller subset of DCs are called "plasmacytoid DCs" (pDCs) because of their similarity to antibody-secreting plasma cells. These cells bear a high number of CD123 cell surface markers, which respond to IL-3 and, in turn, produce type I IFN. Characteristics of the pDCs link them to both lymphoid and myeloid precursors (125). The mechanism by which DCs help establish T-cell memory and tolerance, has yet to be determined, but at least in a mouse asthma model, if pDCs are depleted and animals are exposed to an allergen, then IgE sensitization, airway eosinophilia, and Th2-cell cytokine production occurs, which is not seen in mice with pDCs (126).

In AR, cytokines such as IL-4, IL-5, and IL-13 produced by activated cells play a role in inflammation. In cultures of pDCs and CD4+T cells of grass pollen allergic patients, IL-2, IL-5, IL-10, and IL-13 production is increased and upon exposure to grass allergen, CD4+ cells grow and pDCs will produce IL-4, IL-5, and IL-13 with repeated stimulation (127). This further supports the theory that pDCs have effects on stimulating allergen-specific (memory) Th2 responses in the presence of mucosal inflammation.

In their immature forms, DCs in the periphery of the body primarily function to sample antigen. The maturation of DCs occurs after TLR-ligand stimulation (128), upregulation of MHC classes I and II, and upregulation of costimulatory molecules such as CD40, CD80, and CD86 (129). These mature DCs then go on to interact with naïve CD4+ and CD8+ cells.

Another role of DCs is polarizing of T cells into Th2-type effector cells. In animal models of allergic airway inflammation, dendritic-cell–like APCs resembling epidermal Langerhans cells preferentially uptake antigen and present it to CD4+ cells locally in the lung (130), supporting the work of others showing that DCs act to induce Th2 responses (131,132) and that they are necessary to induce a chronic inflammatory eosinophilic response (133,134).

Langerhans cells, another subset of DCs, are the subpopulation that plays a role in T-cell responses in the nasal submucosa in seasonal allergies (135). Other studies comparing functional DC subtypes in normal human upper airways as opposed to the characterizations made in mouse models found that the majority expressed a macrophage-like phenotype (CD11b+CD14+CD64+CD68+RFD7+) (136).

IMMUNOGLOBULINS

Igs are glycoproteins composed of 82% to 96% polypeptide and 4% to 18% carbohydrate components. They account for approximately 20% of the total plasma proteins. Igs function to tag and aggregate toxins and bacteria. They facilitate the activation of the complement system as well as the activation of macrophages, neutrophils, and lymphocytes to clear foreign materials. Binding of antibody to the Fc receptor of mast cells sensitizes these cells for immediate type hypersensitivity.

Ig diversity is attained via multiple processes. The human heavy chain (V_H), D, and junctional (J_H) heavy chains are found on chromosome 14. There are 46 functional V_H segments per haploid genome, with considerable polymorphism within certain segments. V segments vary in two specific regions called complimentarily-determining regions that form part of the antigen-binding site of antibodies. There are seven families of D segments that code for diversity in the Ig repertoire. Functional J_H segments, six in number, are located downstream of the D region. Combinatorial rearrangement of this large number of genes codes for diversity by utilization of recombinant activation genes (*RAG1* and *RAG2*) to facilitate binding to recombinant signal sequences. DNA strand breakage and rejoining at splice sites account for much of the diversity observed in Ig function; however, the recombination process incorporates additional methods that greatly increase the variety of expressed antibodies, which includes the addition or removal of nucleotides to segments and somatic point mutation of rearranged genes. All completely assembled Ig molecules contain an equal number of heavy (H) and light (L) polypeptide chains (Fig. 25.3). In a healthy individual, there are nine isotypes of Igs and four different classes, they are: IgG, IgA, IgM, and IgE.

In normal adults, IgG, which has the most prominent role in memory immune responses, constitutes approximately 75% of the total serum Igs. The relative concentrations of the four subclasses are as follows: IgG1, 60% to 70%; IgG2, 14% to 20%; IgG3, 4% to 8%; and IgG4, 2% to 6%. IgG can fix complement, with the subclasses' ability to fix complement as follows: IgG3 > IgG1 > IgG2. IgG4,

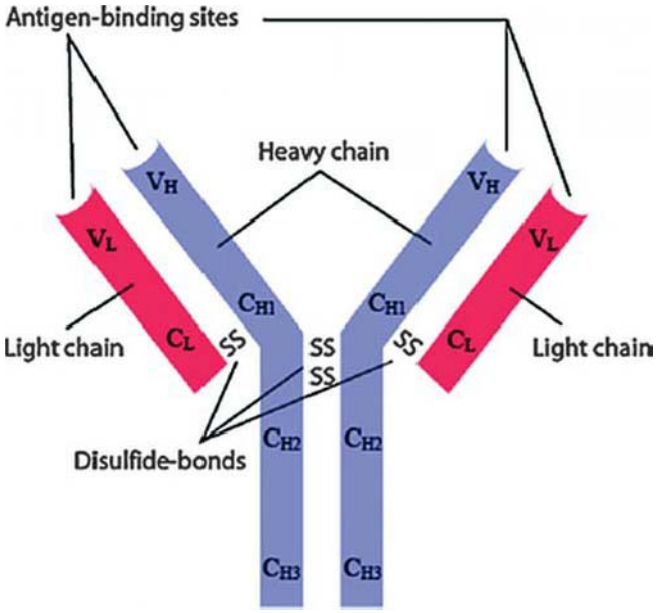

Figure 25.3 Antibody structure. Antibodies are Y-shaped, flexible molecules consisting of two heavy and two light chains linked together by disulfide bonds. The light and heavy chains are composed of constant (CL, CH1, CH2, CH3) and variable (VL, HL) regions. (Adapted from Moser M, Leo O. Key concepts in immunology. *Vaccine* 2010;31;28(Suppl 3):C2–C13.)

although unable to fix complement by the classic pathway, can utilize the alternative complement pathway. IgG4 also plays a role in immunotherapy, as shown in Figure 25.2.

IgA, constituting approximately 15% of the total serum Igs, predominates in body secretions. There are two subclasses, IgA1 and IgA2. The helper T cells in the lymphoid tissues of the gastrointestinal and respiratory tracts switch the B cells from IgM to IgA secretion. Secretory IgA, because of its abundance in saliva, tears, and bronchial and nasal secretions, as well as mucous secretions of the small intestine, provides the primary defense mechanism against local mucosal infections. Its main function may be to prevent access of foreign substances to the general immunologic system. Besides its traditional role in extracellular antibody function, IgA can neutralize viruses intracellularly, can provide an internal mucosal barrier by intercepting antigens and ferrying them through the epithelium, and, after binding to the surfaces of some leukocytes, can activate the alternate pathway of complement activation. Its role in food tolerance to antigens in the digestive system is currently under study. In a study by Frossard et al. (137), a significant increase in the antigen-specific IgA-producing cells was seen in a group of mice tolerized to food allergy.

IgM constitutes 10% of serum Igs and normally exists as a pentamer with a molecular weight of 900,000. IgM antibody predominates in the early immune response and along with IgD is the major Ig expressed on the surface of B cells and is far and away the most efficient Ig in complement fixiation. The enormous size of this pentamer Ig can cause dangerous obstruction in high concentration in areas such as small venules. After an early rise, the IgM response declines and is replaced by IgG of the same antigen specificity. The fetus makes IgM before birth, but maternal IgM is too large to cross the placenta. Thus, IgM antibody to a specific organism in newborn serum indicates intrauterine infection.

IgD is a monomer that is normally present in serum in trace amounts (0.2% of total Igs) and whose function remains unknown. IgD (with IgM) predominates on the surfaces of human B lymphocytes, and thus its most important role may be as a receptor.

Normally, IgE comprises only 0.004% of the total serum Igs, but it binds with very high affinity to mast cells and basophils via the Fc region, thus playing an important role in allergic responses. Like IgD and IgG, IgE normally exists in monomeric form. IgE is produced by B cells after the initiation of two important signals: IL-4 or IL-13 targeting of the *Cε* gene that causes switch recombination, and interaction of activated-T-cell CD40 ligand (CD40L) with CD40 on the surface of B cells to initiate deletional switch recombination (138). Although these mechanisms are not fully understood, the formation of IgE in the atopic or allergic patient plays a major role in the disease process. IgE is also produced locally in nasal mucosa in patients with AR (139).

IgE antibodies fixed to mast cells undergo cell surface cross-linking upon combination with allergen, which then triggers the release of preformed inflammatory mediators such as histamine, tryptase, and protease from mast cells and basophils. IgE probably promotes the survival of mast cells by binding to its high-affinity receptor, *FcεR I*, on the mast cell, which leads to increased expression of antiapoptotic molecules (140). The continued survival of proinflammatory cells in the context of allergic inflammation may be a factor in the chronic symptomatology of the disease even after the removal of allergens. A subunit of the FcεRI receptor, the β chain, probably promotes transport of FcεRI to the surface of mast cells and basophils and hence amplifies the downstream events of the allergic response several-fold in those cells (141). The role of *FcεRIβ* as a candidate gene for atopy modulation is unclear.

IgE also binds to macrophages, neutrophils, eosinophils, and DCs via low affinity receptors. In macrophages, *FcεRI* cross-linking results in production of IL-10. Expression of cell surface *FcεRIα* is present on neutrophils from asthmatic patients (142), indicating that neutrophils may play a role in the allergic response via an IgE-dependent activation mechanism. Human eosinophils were found to secrete IL-10 upon engagement of the receptor (143). Targeting IgE has proven clinically useful, as demonstrated by omalizumab, a monoclonal antibody against IgE, which decrease serum and cell-surface IgE levels and has been useful in the care of severe allergic asthma since approved by the U.S Food and Drug Administration (FDA) in 2003.

Also important are strategies for modulating IgE synthesis by blocking of transcription factors for IgE production. In a mouse model of asthma, mice lacking T-cell–specific

T-box transcription factor (T-bet), a transcription factor that skews toward Th1 and away from Th2 differentiation, had airway changes resembling an asthma phenotype (144). Other studies that under way are those of blocking synthesis of cytokines such as IL-4 and IL-13 that promote production of IgE. Anti-CD23 antibodies in their role of inhibiting IgE production are also being studied.

CYTOKINES, INTERFERONS, AND CHEMOKINES

Cytokines are soluble mediators that have growth, differentiation, and activation functions for immune responses. Cytokines can be grouped into those that are predominantly APCs or T-lymphocyte derived; that predominantly mediate cytotoxic (antiviral and anticancer), humeral, cell-mediated (Th1 and Th17), or allergic immunity (Th2); or that are immunosuppressive (T_{reg} cells) (145). Table 25.2 lists the cytokines produced by lymphocytes, and Table 25.3 is a complete list of cytokines.

Chemokines are a group of small (8 to 12 kD) proteins with the ability to affect cell migration or chemotaxis. These cells include the neutrophils, monocytes, lymphocytes, eosinophils, fibroblasts, and keratinocytes. To date, 52 chemokines and 20 chemokine receptors have been described, which are listed in Table 25.4, and their involvement in diseases in Table 25.5.

TABLE 25.2 Th LYMPHOCYTE FAMILIES

Family	Cytokine Repertoire	Cytokines Involved in Differentiation	Transcription Factors Involved in Differentiation
Th1	IFN-γ, TNF-α, TNF-β, GM-CSF, IL-2, IL-3	**IL-12:** activates STAT4, leading to expression of T-bet; induces IL-18R expression **IL-18:** upregulates IL-12R, further induces IFN-γ expression **IL-27:** activates STAT4, leading to increased expression of T-bet and IFN-γ **IFN-γ:** increases expression of T-bet by increasing expression of STAT1; negative regulator of Th17 and Th2	**T-bet:** master regulator of Th1 cells; potentiates production of IFN-γ and IL-12Rβ2; suppresses Th2 and Th17 differentiation **STAT4:** produced in response to IL-12 and potentiates production of IFN-γ **STAT1:** increases expression of T-bet; negative regulator of Th17
Th2	IL-2, IL-3, IL-4, IL-5, IL-9, IL-13, IL-24, IL-25, IL-31, TNF-α, GM-CSF	**IL-4:** activates STAT6, leading to expression of GATA-3; negative regulator of Th17, IL-19, IL-25, IL-33 **TSLP:** promote differentiation and survival of Th2-like cells	**GATA-3:** master regulator of Th2 cells; potentiates IL-4 expression; suppresses expression of Th1 differentiation and cytokines expression (IFN-γ) **MAF:** contributes to IL-4 production once a Th2 program is established; inhibition of Th17 differentiation **STAT6:** promotes Th2 cell differentiation; negative regulator of T-bet expression and Th1 differentiation **NFAT:** increases transcription of IL-4
Th9	IL-4, IL-9	**TGF-β:** induces the high IL-9 phenotype of Th2-like lymphocytes	
Th17	IL-17 (IL-17A), IL-17F, IL-21, IL-22	**IL-6:** differentiation factor for the generation of Th17 cells TGF-β, IL-21 **IL-23:** support the differentiation and function of Th17 cells in the additional presence of IL-6	**RORγt** (retinoic acid-related orphan nuclear receptor) is the master regulator of Th17 cell differentiation **STAT3:** activated by IL-6 and essential for Th17 differentiation
nT_{reg}/iT_{reg}	IL-10	**TGF-β:** differentiation factor for the generation of nT_{reg} cells **IL-10:** important for differentiation of peripheral iT_{reg} cells, role in nT_{reg} development uncertain **IL-2:** promotes survival, proliferation, and survival of nT_{reg} cells through their constitutive expression of CD25	**FOXP3:** master regulator of thymus-derived nT_{reg} cells
Th3	TGF-β, IL-10

TABLE 25.3 CHARACTERISTICS OF CYTOKINES

Cytokine	Structure	Size Molecular Weight	Receptors	Cell Sources	Cell Targets	Major Functions	Disease Association
IL-1α, IL-1β	Heterodimer	17 kD	IL-1RI, IL-1RII	Macrophages, monocytes, lymphocytes, keratinocytes, microglia, megakaryocytes, neutrophils, fibroblasts, synovial lining cells	T cells, fibroblasts, epithelial and endothelial cells	Induction of proinflammatory proteins, hematopoiesis, differentiation of Th17 cells	Wide range of autoimmune and inflammatory diseases, RA, IBD, psoriasis
IL-1Ra (antagonist)	Heterodimer	16.1–20 kD	IL-1RI, IL-1RII	Monocytes, macrophages, fibroblasts, neutrophils, endothelial and epithelial cells, keratinocytes	T cells, fibroblasts, epithelial and endothelial cells	Antagonism of IL-1	Wide range of autoimmune and inflammatory diseases, RA, IBD, psoriasis
IL-2	Monomer	15.5 kD	IL-2R	CD4+ and CD8+ activated T cells, DCs, NK cells, NKT cells	CD4+ and CD8+ T cells, NK and B cells	Proliferation of effector T and B cells, development of T_{reg} cells, differentiation and proliferation of NK cells and growth factor for B cells	T-cell-mediated autoimmune and inflammatory diseases, X-linked severe combined immunodeficiency 1
IL-3	Monomer	15 kD	IL-3Rα + β c (CD131)	T cells, macrophages, NK cells, mast cells, eosinophils, stromal cells	Erythroid progenitors, granulocyte-macrophages progenitors, CD34+ progenitor cells, basophils, eosinophils	Hematopoietic growth factor, activation of basophils and eosinophils	Role in allergic diseases, different types of cancers, lymphocytic and acute myeloid leukemias
IL-4	Monomer	15 kD	IL-4R type I, IL-4R type II	Th2 cells, basophils, eosinophils, mast cells, NKT cells, γ/δ T cells.	T and B cells	Induction of Th2 differentiation, IgE class switch, upregulation of class II MHC expression on B cells, upregulation of CD23 and IL-4R, survival factor for B and T cells, role in tissue adhesion and inflammation	Inflammatory and autoimmune diseases (allergy/asthma and diabetes mellitus), chronic lymphocytic leukemia diseases
IL-5	Dimer	15 kD	IL-5R	Th2 cells, activated eosinophils and mast cells, Tc2 cells, γ/δ T cells, NK and NKT cells, CD4– ckit– CD3ε– IL2Rα– (Peyer patches)	Eosinophils, basophils, and mast cells	Differentiation and function of myeloid cells, increment of chemotactic activity and adhesion capacity on eosinophils, remodeling and wound healing	Allergy/asthma, hypereosinophilic syndrome
IL-6	Homodimer	19–26 kD	IL-6R, (sIL-6R) gp130	Endothelial cells, fibroblasts, monocytes/macrophages	Hepatocytes, leukocytes, T cells, B cells, hemopoietic cells	Liver: synthesis of acute phase proteins; leukocytes: trafficking, activation; T cell: differentiation, activation, survival; B cell: differentiation, production of IgG, IgM, IgA hematopoiesis	Autoimmune disease, chronic inflammatory disease, B-cell malignancy, SLE, Castleman disease, plasmacytoma/multiple myeloma

IL-7	Monomer	25 kD	IL-7R and sIL-7R	Epithelial cells, keratinocytes, DCs, B cells, and monocytes/macrophages	B, T, and NK cells	Proliferation of pre-B and pro-B cells (mice), megakaryocytes maturation, VDJ recombinations, naive T-cell survival, synthesis induction of inflammatory mediators in monocytes	Allergy/autoimmunity and psoriasis
IL-8	Homodimer	16 kD	CXCR1 and CXCR2	Monocytes, macrophages, neutrophils, lymphocytes, endothelial cells, epithelial cells, fibroblasts, keratinocytes, chondrocytes, synovial cells, hepatocytes	Neutrophils, NK cells, T cells, basophils, eosinophils, endothelial cells	Chemoattractant for neutrophils, NK cells, T cells, basophils, eosinophils; mobilization of hematopoietic stem cells; angiogenesis	Increased levels during inflammatory diseases (RA, psoriasis, bacterial and viral infections)
IL-9	Monomer	14 kD	IL-9R	Th2, Th9, mast cells, and eosinophils	B, T, and mast cells	T and mast cells growth factor, inhibition of Th1 cytokines, proliferation of CD8+ T cells and mast cells, IgE production, chemokine and mucus production in bronchial epithelial cells	Helminth infections, Hodgkin lymphoma, asthma, food allergy
IL-10	Homodimer	20.5 kD, predicted size of precursor protein; 18.6 kD, predicted size mature protein, monomer	IL-10R1/ IL-10R2 complex	T cells, B cells, monocytes, macrophages, DCs	Macrophages, monocytes, T cells, B cells, NK cells, mast cells, DC, and granulocytes	Immune suppression	Cancer, autoimmunity, allergy
IL-11	Monomer	19 kD	IL-11Rα + gp130	Stromal cells: fibroblasts, epithelial cells, endothelial cells, vascular smooth muscle cells, synoviocytes, osteoblasts	Myeloid, erythroid, and megakaryocyte progenitors, osteoclasts, epithelial cells, hepatocytes, macrophages, neurons	Growth factor for myeloid, erythroid, and megakaryocyte progenitors; bone remodeling; protects epithelial cells and connective tissue; induction of acute-phase protein; inhibition of macrophage activity; promotion of neuronal development	Increased during allergic asthma
IL-12 (p35/p40)	Heterodimer	IL-12a p35, 35 kD; IL12b p40, 40 kD	IL-12Rb1 and IL-12Rb2	Monocytes, macrophages, neutrophils, microglia, DCs, B cells	T cells (Th1 cells), NK cells	Induce Th1-cell differentiation and cytotoxicity	Impaired Th1 response with higher susceptibility to intracellular pathogens, use as anticancer agent
IL-13	Monomer	10 kD	IL-13R1α1 and IL-13R1α2	T, NKT, and mast cells, basophils, eosinophils	B cells, mast cells, epithelial cells, eosinophils, smooth muscle cells and macrophages	Switching to IgG4 and IgE, upregulation of CD23, MHC-II on B cells, induction of CD11b, CD11c, CD18, CD29; CD23, and MHC-II on monocytes, activation of eosinophils and mast cells, recruitment and survival of eosinophils, defense against parasite infections	Asthma, AR, fibrosis

(Continued)

TABLE 25.3 CHARACTERISTICS OF CYTOKINES (*Continued*)

Cytokine	Structure	Size Molecular Weight	Receptors	Cell Sources	Cell Targets	Major Functions	Disease Association
IL-14	Monomer	53 kD	IL-14R	T cells, T-cell clones, B-lineage and T-lineage lymphoma cell lines	B cells, certain leukemia cells	Proliferation of activated B cells	Autoimmunity, lymphoma genesis
IL-15	Monomer	14–15 kD	IL-15R	Monocytes, activated CD4+ T cells, keratinocytes, skeletal muscle cells	T, NK, and NKT cells	T-cell activation, proliferation and activation of NK cells, differentiation of γ/δ T cells, suppression of IL-2 induced AICD of T cells, homeostasis of CD8+ memory, NK and NKT cells, enhancement of Th2 differentiation and suppression of AR	Autoimmune and inflammatory diseases
IL-16	Homotetramer	56 kD	CD4	T cells, eosinophils, mast cells, eosinophils, monocytes, DCs, fibroblasts, epithelial cells	T cells, monocytes, macrophages, eosinophils	Chemotaxis, modulation of T-cell response	Increased during various inflammatory and infectious diseases including atopic eczema, allergic asthma, Crohn disease, RA, hepatitis C infection, tuberculosis; inhibits HIV infection
IL-17A	Cysteine knot, homodimer or heterodimer	35 kD	IL-17RA (=IL-17R)	Th17 cells, CD8+ T cells, NK cells, NKT cells, γδ T cells, neutrophils	Epithelial/endothelial cells, fibroblasts, osteoblasts, monocytes, macrophages	Induction of proinflammatory cytokines, chemokines, and metalloproteases; recruitment of neutrophils	RA, MS, IBD, psoriasis, allergic asthma, atopic dermatitis, contact hypersensitivity
IL-17B,C,D	Cysteine knot, homodimer	41, 40, 52 kD	For IL-17 B, IL-17RB (=IL-17H1, IL25R); for IL-17C and D, not known	IL-17B: neuronal cells, chondrocytes; IL-17C: immune cells under certain conditions; IL-17D: resting B and T cells	Monocytes, endothelial cells, myofibroblasts	Induction of proinflammatory cytokines, chemokines, and metalloproteases; IL-17B: chondrogenesis and osteogenesis	RA, allergic asthma, inflammatory cardiomyopathy, Wegener granuloma
IL-17F	Cysteine knot, homodimer or heterodimer	44 kD	IL-17RA (=IL-17R) and IL-17RC (=IL-17RL)	Th17 cells, CD8+ T cells, NK cells, NKT cells, γδ T cells, neutrophils	Epithelial/endothelial cells, fibroblasts, osteoblasts, monocytes, macrophages	Induction of proinflammatory cytokines, chemokines, and metalloproteases; recruitment of neutrophils	IBD, psoriasis, allergic asthma
IL-18	Heterodimer	22.3 kD	IL-18R	Wide range of cells, mainly macrophages, Kupffer cells, keratinocytes, osteoblasts, astrocytes, DCs	Variety of cells, T cells, NK cells, macrophages, epithelial cells, chondrocytes	Induction of IFN-γ in presence of IL-12, enhances NK cell cytotoxicity, promoting Th1 or Th2–cell responses depending cytokine milieu	Autoimmune diseases or inflammatory disorders, RA, psoriasis, MS, type I diabetes

IL-19	Monomer	20.5 kD, predicted size of precursor; 17 kD, predicted size of mature protein; 35–40 kD, found in transfected cells, glycosylated	IL20R1/IL-20R2	Monocytes, keratinocytes, airway epithelial cells and B cells	Keratinocytes	Unknown	Psoriasis
IL-20	Monomer	20 kD, predicted size of precursor; 17.5 kD, predicted size of mature protein	IL-20R1/ IL-20R2 and IL-22R1/ IL-20R2	Monocytes, keratinocytes, epithelial and endothelial cells	Keratinocytes, monocytes	Role in skin biology	Psoriasis, RA, atherosclerosis
IL-21	4-Helix bundle, monomer	15 kD	IL-21R	T cells (predominantly Th17), NKT cells	CD4+ T cells, CD8+ T cells, B cells, DCs, macrophages, keratinocytes	Regulation of proliferation, differentiation, apoptosis, antibody isotype balance, cytotoxic activity	Cancer, SLE, RA
IL-22	6 Antiparallel α-helices, monomer	23 kD	IL-10R2 chain and IL-22R1 chain	Activated T cells (predominantly Th17), NKT cells (NK-22)	Tissue cells like keratinocytes, subepithelial myofibroblasts	Pathogen defense, wound healing, tissue reorganization	Psoriasis, IBD, cancer
IL-23 (p19+p40)	Heterodimer	IL-12b p40, 40 kD; IL-23 p19, 19 kD	IL-12Rb1 and IL-23R	Macrophages, activated DCs	T cells (Th17 cells) and macrophages	Stimulate production of proinflammatory IL-17 and promote memory T-cell proliferation	Susceptibility to extracellular pathogens, exacerbate organ-specific autoimmune inflammation
IL-24	Homodimer and monomer	23.8 kD, predicted size of unprocessed precursor; 18 kD, unglycosylated mature protein; 35 kD, observed size of secreted IL-24, glycosylated	IL20R1/IL-20R2 and IL-22R1/ IL-20R2	Melanocytes, T cells, monocytes	Cancer cells	Tumor suppression	Melanoma, psoriasis
IL-25 (IL-17E)	Homodimer	17 kD	IL-17RA and IL-17RB	Th2 cells, mast and epithelial cells, eosinophils and basophils from atopic individuals	Th2 memory cells	Induction of Th2 responses, IgE, IgG1, IL-4, IL-5, IL-13, and IL-9 production	Gastrointestinal disorders, asthma
IL-26	6 α-Helices, homodimer	38 kD	IL-10R2 chain and IL-20R1 chain	Activated T cells (predominantly Th17), NKT cells	Epithelial cells	Activation and regulation of epithelial cells	IBD
IL-27 (p28+EBI3)	Heterodimer	IL-27a p28, 28 kD; IL-27b EBI3, 25.4 kD	WSX-1 and gp130	Activated DCs, macrophages, epithelial cells	T cells, NK cells	Induction of Tbet promoting Th1-cell differentiation, inhibition of Th17-cell response via STAT1	Immune pathology because of uncontrolled inflammatory response
IL-28A/B/ IL-29 (IFN λ family)	Monomer	IL-28A, 22.3 kD; IL-28B, 22.2 kD; IL-29, 21.9 kD	IL-28R1/ IL-10R2	Monocyte-derived DCs	Most cell types	Antiviral immunity	Role in allergic and autoimmune diseases
IL-30 (p28 subunit of IL-27)							

(Continued)

TABLE 25.3 CHARACTERISTICS OF CYTOKINES (*Continued*)

Cytokine	Structure	Size Molecular Weight	Receptors	Cell Sources	Cell Targets	Major Functions	Disease Association
IL-31	4-Helix bundle	24 kD	IL-31RA/ OSMRβ	Activated CD4+ T cells (mainly Th2) and CD8+ T cells	Keratinocytes, epithelial cells, monocytes, eosinophils, basophils	Induction of IL-6, IL-8, CXCL1, CXCL8, CC chemokine ligand 2, and CC chemokine ligand 8 production in eosinophils, upregulates chemokine mRNA expression in keratinocytes, expression of growth factors and chemokines in epithelial cells, inhibition of proliferation and apoptosis in epithelial cells	Atopic dermatitis, allergic contact dermatitis, prurigo nodularis, chronic spontaneous urticaria, nonatopic eczema, asthma, other inflammatory disorders
IL-32	Unknown	14.9–26.6 kD	Unknown	Monocytes, macrophages, NK cells, T cells, epithelial cells	Macrophages, DCs, T cells, PBMCs, monocytes	Induction of TNF-α, IL-8, and IL-6, apoptosis	RA, IBD, autoimmune diseases
IL-33	β-Trefoil fold	30 kD (active form, 18 kD)	ST2	Necrotic cells and nuocytes	Basophils, mast cells, eosinophils, NK cells, NKT cells, Th2 cells, DCs, nuocytes	Transcriptional repressor activity, induction of Th2 inflammation on mucosal tissues	Autoimmune and cardiovascular diseases, asthma, gastrointestinal tract and lung disorders
IL-34	Homodimer	39 kD monomers	CSF1R	Heart, brain, liver, kidney, spleen, thymus, testes, ovary, small intestine, prostate, colon, most abundant in spleen	Monocytes, macrophages	Proliferation	
IL-35 (p35+EBI3)	Heterodimer	60 kD	Unknown	T_{reg} cells	Different T-cell subsets	Proliferation of T_{reg} cells and inhibition of Th17-cell function, suppression of inflammatory responses	IBD, collagen-induced arthritis
IL-37	Unknown	17–24 kD	IL-18Rα?	Monocytes, tonsil plasma cells, breast carcinoma cells	Intracellular mechanism manner and DC	Suppression of proinflammatory cytokines and inhibition of DC activation	RA
IFN-γ	Homodimer	34 kD	IFNGR1/ IFNGR2	NK and NKT cells, macrophages, myelomonocytic cells, Th1 cells, CTL and B cells	Epithelial cells, macrophages, DCs, NK cells, T and B cells	Antiviral properties, promotes cytotoxic activity, Th1 differentiation, upregulation of MHC class I and II, inhibition of cell growth, proapoptotic effects and control of AICD, regulation of local leukocyte–endothelial interaction, and enhancement of microbial killing ability	Susceptibility to intracellular pathogen infection and tumor development, type 1 diabetes, RA, experimental autoimmune encephalomyelitis

AICD, Activation-induced cell death; CTL, cytotoxic T lymphocyte; NK, natural killer; OSMRb, oncostatin-M receptor b; sIL-6R, soluble IL-6 receptor; STAT1, signal transducer and activator of transcription.

DEVELOPMENT OF ALLERGY

The development of AR, as that of other allergic conditions, pivots on the interplay between genetic predisposition and the timing of environmental exposures. The environmental triggers include dust mite, molds, animal dander, and the pollens of trees, grasses, and weeds (146). A family history of atopic diseases is a risk factor for the development of AR, asthma, and atopic dermatitis. Studies on AR among twins and within atopic individuals clearly indicate a genetic contribution for its development (147). In monozygous twins, a 45% to 60% concordance for AR is observed, which drops to 25% in cases of dizygotic twins (148).

Subjects with a family history of asthma, eczema, hay fever, and urticaria and a positive skin test are referred to as atopic. Allergic parents have a higher than usual proportion of allergic children; 50% of children with two allergic parents will develop an allergy. With only one allergic parent, the chance is about 30%. Thus, the family history represents an important risk factor for allergic disease and indicates an important question to address when evaluating a child with possible allergies.

The genetics of asthma has received more attention than the genetics of AR (149). Among these studies, a number of candidate genes and their polymorphisms have been targeted with variable effect, sizes, and levels of significance (Table 25.6). A meta-analysis for the genetics of AR provided evidence for an overall association between the A allele of IL13 SNP (single nucleotide polymorphism) and an increased risk of AR, especially in mixed-age populations (150).

There are several environmental changes that are epidemiologically linked with allergy and affect fetal gene expression and immune function (151–154). These include, but are not limited to, the microbial burden (155,156), dietary changes (157,158), and environmental pollutants (159,160). These epigenetic changes can be passed on to subsequent generations (Fig. 25.4).

Lifestyle changes that occurred in the past few decades probably increased the development of atopy and increased the prevalence of allergy in the Western countries (161). Maternal diet, including decreases in polyunsaturated fatty acids (152), soluble fiber (162), antioxidants (163), and folate (164) during pregnancy, is associated with an increase in asthma and allergic disease. Vitamin D may affect the development of allergies and asthma early in life although the studies are conflicting (165). High maternal intake of vitamin D during pregnancy and by infants in their first year of life was shown to be associated both negatively (166,167) and positively (168) with wheeze or asthma in children. Paracetamol (Tylenol) use increased the risk of asthma (169–172), especially when used in the first year of life (173). Paracetamol reduces the levels of the antioxidant glutathione in immune cells, which results

in increased oxidative stress, decreased antioxidant effects, and could lead to the promotion of Th2 allergic inflammation (169), as well as increased viral loads (174).

The Hygiene Hypothesis

Epidemiologic studies provide evidence for the "hygiene hypothesis" that associates reductions of infectious diseases in developed countries with the rise of allergic and atopic diseases. The "hygiene hypothesis" postulates that infections during infancy may protect against AR and atopy by downregulating the production of IgE (175–180). There is an inverse relationship between number of siblings and atopy, which implicates greater exposure to infectious agents as being protective toward the development of atopy later in life; that is, the youngest sibling has the least likelihood of developing allergic disease. Pet ownership decreases the development of asthma later in life, in a dose response relationship, with the greater the number of pets, the less the risk of later asthma. However, Svanes et al. (181) showed that cat ownership increased the development of adult asthma in sensitized children, with a stronger association in communities with less exposure to cats. In contrast, they found that dog ownership seemed to promote the development of nonallergic asthma in adulthood, but protected against allergic asthma (181).

In a cross-sectional study of rural farming communities in Austria, Germany, and Switzerland, exposure of children less than 1 year old to stables and farm milk was associated with increased protection against the development of asthma, AR, and atopic sensitization (182). The farming environment is associated with reduction in Th2-dependent antibody isotype switching on exposure to common inhalant allergens in human subjects. This process is thought to be mediated by exposure to endotoxin acting through TLR4. Genetic variants at the TLR4 receptor are associated with a blunted response to lipopolysaccharide in humans (183).

In a study of TLR4-deficient mice, sensitization and challenge with ovalbumin (OVA) produced significantly reduced OVA-specific IgG1 and no IgE antibody responses (184). In the same study, investigators showed that different doses of LPS conferred divergent abilities to develop Th1- or Th2-predominant responses. The inverse association between farm milk consumption and allergic diseases is mediated via CD 14-activated innate-immune mechanisms (185).

Other supporting evidence for the hygiene hypothesis includes early day care attendance, before 3 months of age, with a reduction in the development of asthma and atopy in later childhood, and reduction of IgE levels (186). In another large cohort study conducted in northern Europe, individuals were tested for seven

common infections. It was shown that those with less than three specific IgG antibodies were almost twice as likely to have atopic symptoms (187). Controversy still exists on the use of antibiotics in infancy and the development of asthma (188). Although these and other studies are impressive, the "hygiene hypothesis" as the primary reason for the increased prevalence of AR is controversial.

The Allergic Response

AR develops after sensitization to allergens. Allergens such as pollens, grasses, dander, and mold are deposited on mucosal surfaces. After antigen deposition, DCs sample antigen and migrate to the lymph nodes, where they present antigen to sensitize T cells. Recent studies have implicated certain cytokines as aiding in the sensitization process. Iwasaki et al. (189) showed that, in TNF-α knockout mice, sensitization was less robust than that induced in wild-type mice. Decreased mRNA production of IL-4, IL-10, and eotaxin in the nasal mucosa as well as eosinophil recruitment in TNF-α knockout mice, point to a potential contribution of TNF-α to the development of AR.

When an allergen binds to a specific IgM on an APC, such as Langerhans cells in the epidermis, the allergen is internalized, broken up in lysosomes, and presented as small fragments in the context of cell-surface MHC-II complexes. During this interaction in the local lymphoid tissue, the complexes are presented to Th cells. Th cells subsequently secrete cytokines such as IL-4. T cells exhibit IL-4 receptor and CD40 ligand on their surfaces. IL-4 from T cells binds to the IL-4 receptor on B lymphocytes. Allergen sensitization in the nose results in IgE production in the context of these cytokines.

Germ line transcription of the heavy chain locus results in an isotype switch from IgM to IgE and the synthesis of IgE (118) (Fig. 25.5). Interestingly, it is now thought that allergic individuals possess a mucosal environment that favors class switching from IgG to IgE, and indeed, that the isotype switch occurs within the local environment of the mucosa (139). The importance of IgE in the allergic reaction was clearly demonstrated by the successful reduction of the allergic reaction by use of anti-IgE antibodies (190).

IgE-mediated nasal mucosal responses in response to antigen challenge occur in an early and a late phase. In the early response, mast cells predominate (Fig. 25.6). Activation of mast cells produces the cardinal symptoms of sneezing, itching, rhinorrhea, and congestion. The late response occurs hours after the early response, during which numerous cells are recruited and interact. These interactions not only generate symptoms, primarily congestion, but lead to the production of additional allergen-specific IgE and to increased responsiveness to subsequent allergen (priming) and exposure to irritants (hyperresponsiveness) (191–193).

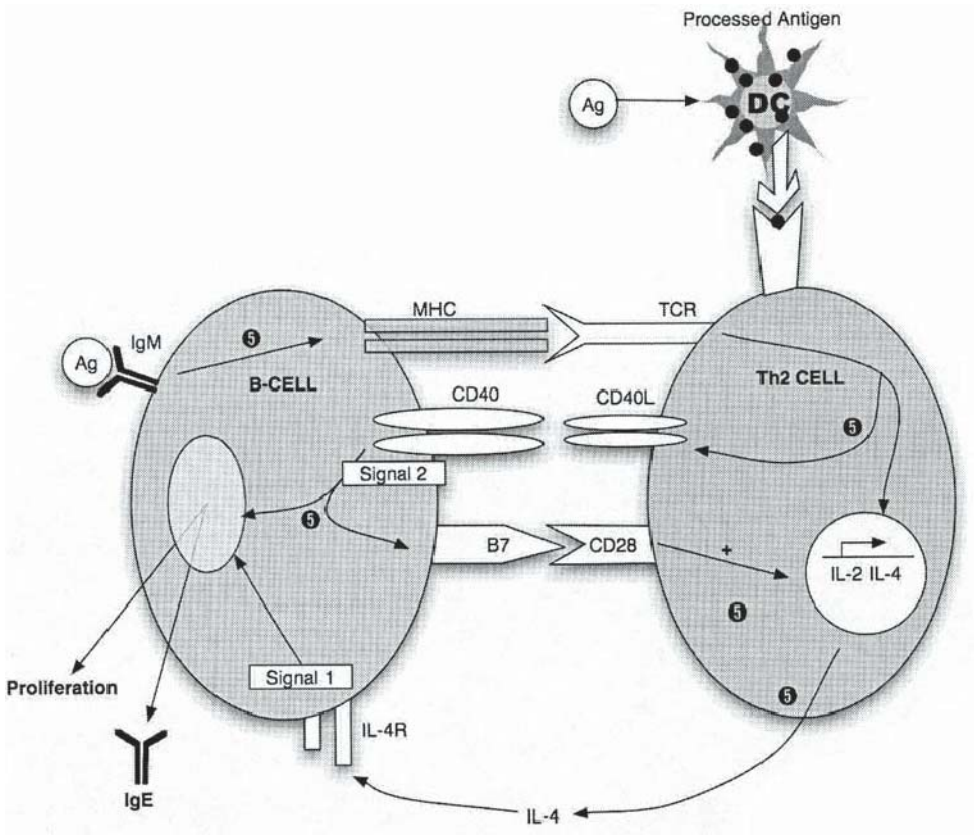

Figure 25.5 IgE development: Signal 1: IL-4 interaction with IL-4 receptor on B cell. Signal 2: costimulatory signal of CD40 on B cell with CD40L on Th2 cell.

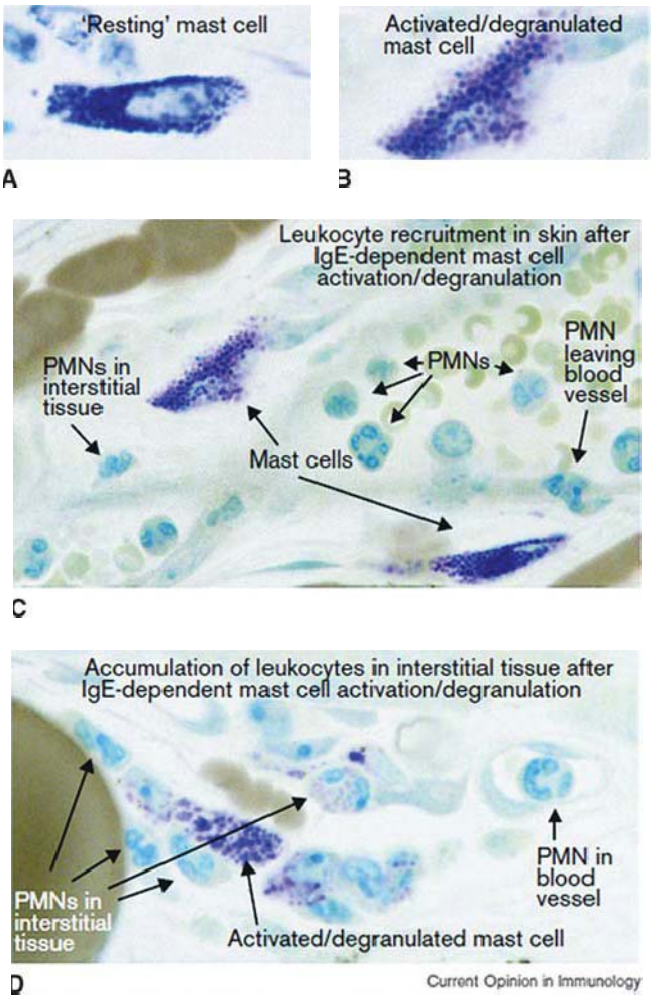

Figure 25.6 IgE-dependent activation of mast cells can induce leukocyte recruitment to sites of allergic responses. The figure shows the degranulation of mast cells and the subsequent recruitment of leukocytes (particularly polymorphonuclear leukocytes [PMNs]) from adjacent vessels. Mice were sensitized by intradermal injection of DNP-specific IgE and were challenged 24 hours later with DNP–HAS intravenously. **A:** Resting and **(B)** activated mast cells can readily be distinguished. The figure illustrates that mast cells **(C)** not only contribute to leukocyte recruitment and migration out of blood vessels in the early phase of an allergic response, but **(D)** are also involved in orchestrating the accumulation of leukocytes in the interstitium of the dermis; these are also characteristic features of later stages of allergic inflammation in humans (i.e., during LPRs and chronic allergic inflammation). Photomicrographs (by J Wedemeyer) are of 1 mm, Epon-embedded, Giemsa-stained sections of ear skin **(A)** before, **(B and C)** at 6 hours, or **(D)** at 8 hours after induction of IgE-dependent passive cutaneous anaphylaxis. Original magnifications were approximately 2,000× **(A and B)** and approximately 1,000× **(C and D)**. (Adapted from Wedemeyer J, Tsai M, Galli SJ. Roles of mast cells and basophils in innate and acquired immunity. *Curr Opin Immunol* 2000;12:624–631.)

The Early Response

The early response in a sensitized host occurs within minutes after exposure to antigen. Patients first sense itching, followed by sneezing, rhinorrhea, watering of the eyes, and then, nasal congestion. A large part of this response except for the congestion is due to the release of histamine and results in vasodilation, vasculature leakage of fluids, glandular, and neural stimulation.

Role of the Mast Cell

Mast cells are divided into two subtypes based upon their content of proteases. Both subtypes contain histamine and exist in the nasal mucosa. Products of mast cells include, but are not limited to, histamine, lipid mediators such as PGs and leukotrienes, chemokines such as eotaxin and RANTES, as well as cytokines IL-3, IL-4, TNF-α, GM-CSF, and MIP-1α.

Mast cells are affected by local cytokines that influence their development, maturation, and death. The cytokine responsible for mast cell growth and proliferation is the stem cell factor (SCF or c-kit ligand) (194). SCF induces histamine release from mast cells, but inconsistently from basophils, and is derived from bone marrow stromal cells, endothelial cells, and fibroblasts. Other cytokines also play a role in mast cell proliferation, including IL-3, IL-5, IL-9, IL-10, IL-11, and nerve growth factor (NGF) (195–199).

Mast cells play important roles in the early response and may play a role in the late response to allergen challenge, as demonstrated in Figure 25.6. Antigen-specific IgE has the ability to bind with high-affinity receptors on mast cells on mucosal surfaces. On exposure to antigen, the antigen-specific IgE on the surface of mast cells cross-links, causing an influx of calcium ions. This process results in the exocytosis of granular content, with the release of preformed mediators such as histamine, heparin, and proteolytic enzymes (tryptase and β-glucosaminidase).

The Late Response

The late response to nasal challenge with antigen refers to the symptoms and inflammatory events that occur hours after antigen exposure. The eosinophils respond to IL-5 produced by T cells, and T cells are likewise activated to facilitate a cascade of events that precipitate the local inflammatory reactions seen in the late response. IL-4 released by mast cells and T helper cells, also contributes to this cascade of events.

In response to IL-4, IL-1β, or TNF-α, local epithelia upregulate very late antigen 4 and ICAM-1 on their surfaces (Fig. 25.7). In concert, T cells, basophils, monocytes, and eosinophils are recruited via vascular cell adhesion molecule 1 (VCAM-1) or lymphocyte function-associated antigen 1 ligands to sites of inflammation. In particular, VCAM-1 and E-selectin have been found to be increased on vascular endothelium of patients with AR, whereas ICAM-1 was found to correlate with E-selectin upregulation (200). RANTES and eotaxin act to recruit T cells and eosinophils into the nasal mucosa. TGF-β has also been found to be upregulated on epithelia of the inferior turbinates of atopic patients and patients with rhinitis, suggesting a possible role for TGF-β in chemoattraction and retention of mast cells in rhinitis (201). Eotaxin in nasal lavages of patients with AR, in particular, was found to correlate with eosinophil recruitment in the mucosa (202). Eotaxin administered intranasally to patients with AR increased eosinophil levels in the mucosa (203).

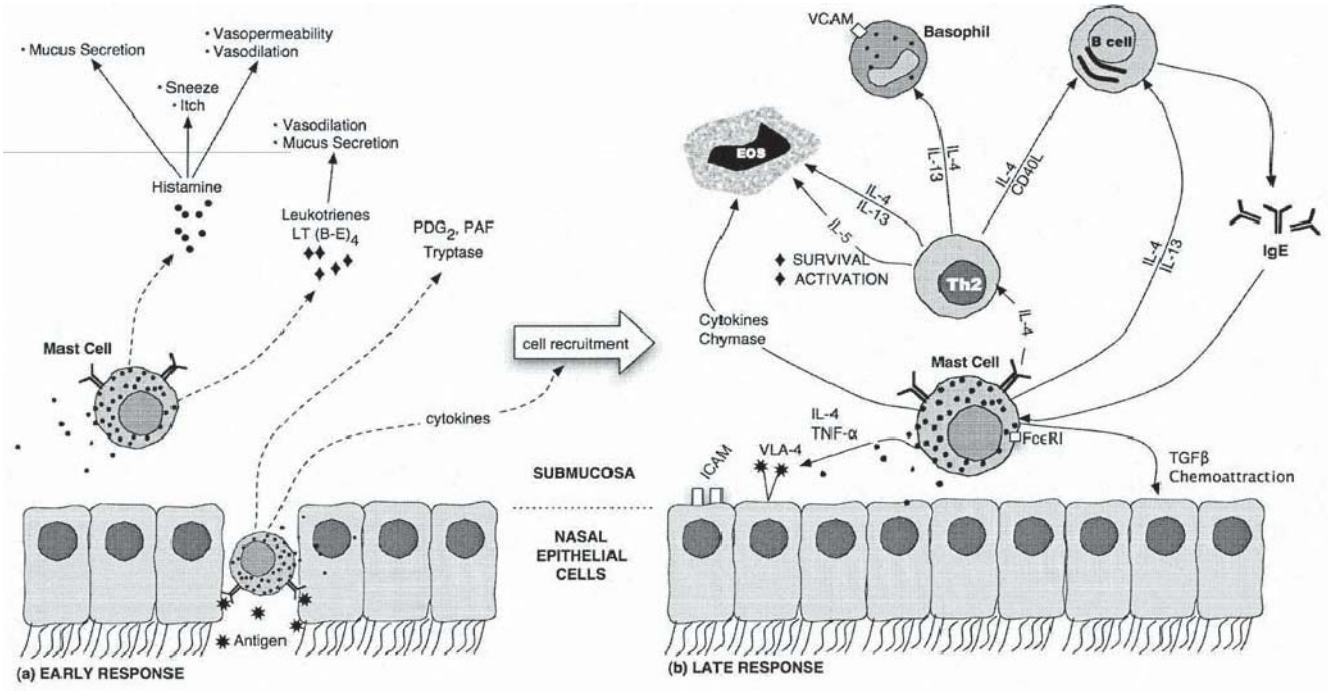

Figure 25.7 **A:** Early response: In the early response to nasal allergen challenge, mast cell activation causes symptoms secondary to mediator release. **B:** Late response: In the late response to allergen challenge, cell recruitment via cytokines causes the accumulation of multiple inflammatory cells in the mucosa, which in turn release mediators that lead to symptoms, hyper responsiveness to irritants, and priming (increased responsiveness to antigen). PAF, platelet activating factor; VLA, very late antigen.

Intracellular and cell-surface changes on endothelium facilitate transendothelial migration of cells. Platelet endothelial cell adhesion molecule 1 (PECAM-1)-deficient endothelium *in vitro* and *in vivo* showed delayed resolution of vascular permeability, suggesting that proinflammatory conditions are conducive to transmigration of inflammatory cells (204). Vascular endothelium cadherin is a transmembrane actin-associated, calcium-dependent adhesion molecule localized at endothelial junctions, and is thought to modulate endothelial permeability (205). During the last decade, there has been general agreement that cells are tethered via interactions between leukocytes and endothelial ligands and are slowed down by "rolling" along the surface of the endothelium, at which point they adhere and are then transmigrated through gap junctions of endothelial cells, a process termed the paracellular pathway. An alternative theory was also reported when leukocytes were shown to cross the endothelium in a transcellular pathway. Figure 25.8 demonstrates these two theories (206).

As highlighted above, the inflammatory processes are numerous, and they overlap in function, adding to complexity and increasing the difficulty in individually defining the exact contribution and importance of each mediator. Interactions that occur during the late response will not only generate symptoms, but lead to the production of additional allergen-specific IgE and to increased responsiveness to subsequent allergen (priming) and irritant exposure (hypersensitivity).

Nonspecific hyperresponsiveness is one of the clinical characteristics of allergic inflammation. Upon infiltration of the nasal mucosa with eosinophils, it becomes hyperactive to normal stimuli and causes nasal symptoms such as sneezing, rhinorrhea, nasal itching, and obstruction (207). Patients with AR will exhibit hyperresponsiveness to nonspecific stimuli such as tobacco or cold, dry air.

THE NEURAL COMPONENT OF ALLERGY

The nose is innervated by afferent, efferent, and postganglionic autonomic nerves. An example of a coordinated neural response is the nasal cycle, a physiologic phenomenon observed more than a century ago (208) that has been confirmed with the use of acoustic rhinomanometry (209) and magnetic resonance imaging (MRI) (210). The nasal cycle is the periodic congestion and decongestion of the nasal venous sinusoids that lead to partial obstruction and patency of each nostril, in reciprocating manner over approximately 4 to 6 hour intervals. Normal individuals are unaware of it because the total nasal resistance remains constant. Patients with rhinitis often describe alternating nasal congestion, which represents the nasal cycle in a compromised airway.

The nasonasal reflex refers to the unilateral stimulation of one nasal passage that ultimately leads to bilateral efferent reflexes, which are identified by their effects in the contralateral nostril. It occurs in response to allergen, histamine, cold, dry air, and capsaicin. The contralateral nostril secretions are 60% of the challenge side after

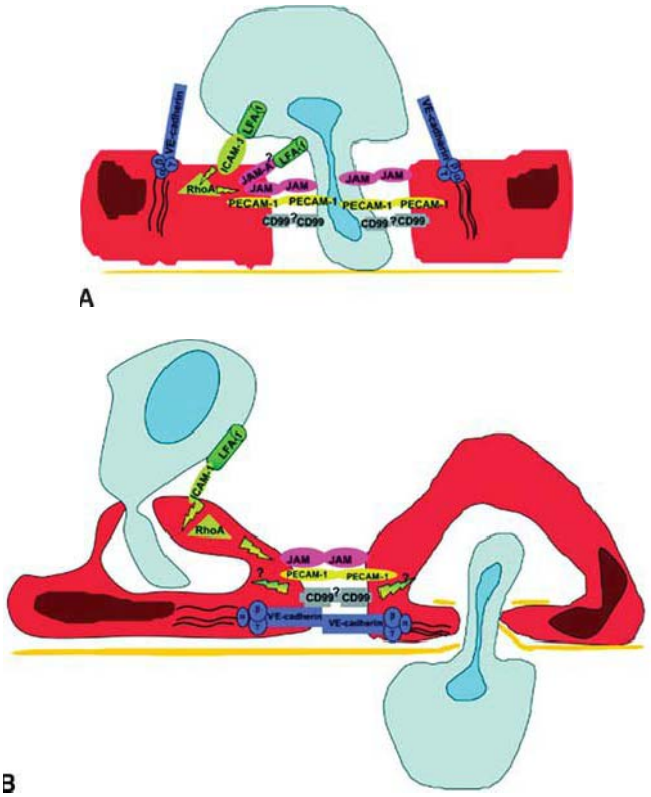

Figure 25.8 Alternative passageways of leukocyte migration across the endothelium. Leukocytes firmly adhere to endothelial ICAM-1, which, via its cytoplasmic tail, delivers a RhoA-mediated signal into the endothelial cell, allowing the leukocyte to migrate either paracellularly through the interendothelial cell junction or transcellularly through the endothelial cell proper. **A:** During paracellular migration, leukocytes encounter homophilic interactions with junctional molecules such as PECAM-1, members of the JAM family, and perhaps CD99 and guiding them through the intercellular cleft, whereas VE-cadherin redistributes to the endothelial cell surface. **B:** Although there is a lack of specific molecular proof for a transcellular route of leukocyte migration across the endothelium, it is speculated that the same molecules investigated for junctional migration trigger the intraendothelial signals required for transcellular migration. (Adapted from Engelhardt B, Wolburg H. Mini-review: transendothelial migration of leukocytes: through the front door or around the side of the house? *Eur J Immunol* 2004;34:2955–2963.)

unilateral histamine provocations. This reflex was shown to be inhibited by cocaine anesthesia to the ipsilateral trigeminal nerves with the efferent limb (parasympathetic) blocked by topical anticholinergic drugs or vidian neurectomy (211).

A nasal–ocular reflex has been shown to exist. Stimulation of the nasal mucosa produces both nasal and ocular symptoms. A topical antihistamine applied in the nose reduces the nasal ocular reflex, suggesting that histamine released in the nose initiates the reflex. The reflex explains how intranasal steroids can eliminate ocular symptoms without being absorbed systematically (212).

Neuropeptides and Neurogenic Inflammation

The secretion of neuropeptides such as tachykinins and neurokinin A (213) are thought to play a modulating role in the pathogenesis of AR through a mechanism called neurogenic inflammation. NGF plays a role in the early response to allergens by inducing maturation, stimulation, and consequent activation of mast cells and release of mediators (214).

NGF promoted allergic responses in a mouse model of asthma by increasing eosinophil and lymphocyte recruitment into the lungs, as well as by the local generation of IL-4 and IL-5, after OVA challenges (215), and is increased in bronchial biopsy specimens after allergen challenge (216).

NGF augments the production of substance P (SP) by neurons and SP is increased in mucosal nerve fibers of patients with seasonal AR (217). SP's actual role in modulating inflammatory migration is unclear (218). Although SP does increase TNF-α and IL-12 production by monocytes and macrophages, it can degranulate mast cells (219).

Neurotrophins, a family of homologous growth factors initially discovered in the nervous system, such as NGF and brain-derived neurotrophic factor, are highly upregulated during allergic inflammation. Neurotrophins are secreted by eosinophils and submucosal glands of the nasal mucosa increase angiogenesis and prolong eosinophil survival in the lungs, increase production of specific IgE, and promote Th2 cytokine predominance (220,221).

Diagnosis

The history and physical examination suggest the diagnosis of AR and both *in vivo* and *in vitro* assays are available to test for allergy; however, there are many more positive allergic tests than allergic individuals (2). The gold standard for allergy testing is *in vivo* antigen-specific skin testing, which is a semiquantitative measurement of the early-phase hypersensitivity reaction. The antigens chosen for testing are based on the patient's medical history plus a screen of common antigens in the local environment. On skin testing, in a sensitized patient, a wheal and flare will occur and usually reach a maximum size in about 20 minutes. Allergy skin testing is suppressed by antihistamines. Thus patients are asked to avoid antihistamines for at least 72 hours before testing. The risk of anaphylaxis with skin testing is small, while large local reactions are more common and all together are reported at a rate of 0.02% to 1.40% (222,223).
